THURSDAY, NOVEMBER 7, 1895.

THE GAY SCIENCE OF ARITHMETIC.

L'Arithmétique Amusante. Par Édouard Lucas. Pp. i.–viii. 1–266. (Paris: Gauthier-Villars et Fils, 1895.)

Traité d'Aritmétique. Par C.-A. Laisant et E. Lemoine. Pp. i.–viii. 1–174. (Paris: Gauthier-Villars et Fils, 1895.)

BY the premature death of Édouard Lucas the world lost at once a wit, a scholar, and an original mathematician. This somewhat rare combination of qualities is evident in all his work, and especially in the inimitable "Récréations Mathématiques," which, to those who are able to appreciate it, will always be one of the most entertaining of books. The interest of the problems themselves, the lucidity with which they are discussed, and the brilliant appropriateness of the author's dedications and mottoes, combine to invest the work with a charm peculiarly its own.

It will be remembered that, shortly after Lucas's death, a commission was appointed by the Mathematical Society of France, consisting of the President of the Society for the time being and MM. Delannoy, Laisant and Lemoine, for the purpose of examining and classifying the unpublished manuscripts of the deceased mathematician. Two additional volumes of the "Récréations" were found practically ready for press, and these were published by the commission in 1893 and 1894 respectively. Although they unavoidably suffer to some extent from the lack of the author's final revision (for instance, we miss the usual witty dedication in some cases), these additional volumes are well worthy to rank with their predecessors.

The first of the books now under review is edited by the same commission, and is uniform in size and style with the "Récréations." It is, indeed, described on the title-page (presumably by the editors) as an introduction to the former work; but this, though true in a sense, is rather misleading. It appears from the editors' preface that, so long ago as 1885, Lucas had in preparation a book to be called "l'Arithmétique amusante," and three manuscript note-books bearing this title were found among his papers. The book now published, or rather the first part of it (pp. 1–186), contains the text of these note-books; the remainder consists of a series of four notes, which form a kind of supplement to the "Récréations," and complete the publication of all that Lucas has left relating to this subject.

By far the greater portion of the first part of the book has already appeared, nearly verbatim, in the "Récreations"; the rest consists partly of arithmetical curiosities, such as

$$8 \times 123456789 + 9 = 987654321,$$

and partly of well-known tricks and puzzles, some of which are not even arithmetical; as, for instance, how to convert a 3 into a 5 by a single stroke of the pen. This may be amusing, but is not arithmetic.

Mathematicians in search of novelty will turn with more interest to the notes which fill up the remainder of the volume. Note i. is the text of an address delivered by Lucas on August 4, 1885, at the prize-day of the Lycée Saint-Louis. Note ii. contains two interesting modifications of the problem of the jealous husbands and their wives. Note iii. gives a brief account of the scientific games invented by Lucas. Note iv., which is the most important, comprises different fragments relating to the "Récréations." These are six in number, and deal with the problem of the eight queens, games with ribbons, magic squares and cubes, and the knight's tour. The last problem, in particular, is discussed at some length.

It will be seen from what has been said that the appearance of this book adds little to Lucas's reputation, although, of course, it does nothing to diminish it. In preparing it for publication, the editors have performed a pious duty, for which they deserve our grateful acknowledgments; and the work is likely to appeal successfully to two classes of readers. The happy possessors of the "Récréations" will not rest until they have procured this supplementary volume for the sake of the notes, or for the æsthetic purpose of completing their set; while those who are not so fortunate will be able to make the acquaintance of the author in a comparatively easy and inexpensive way. It is only fair to warn them that, in all probability, they will feel constrained to buy the larger work afterwards.

The treatise of MM. Laisant and Lemoine is intended to serve a double purpose: to provide a strictly scientific introduction to the science of arithmetic, and to exemplify a system of orthography which has been adopted by the "Société filologique française." This is not the place to discuss the system of spelling which is advocated: suffice it to say that it is one of those compromising systems which, while rebelling against tradition, stop short, by a long way, of a strictly phonetic orthography. The consequence is a mass of inconsistency which has not even the excuse of a historical development: thus, for instance, "philosophie" becomes "filosofie," while "science" retains its traditional form. Again, "commun" is changed into "comun," while "irréductible" is left alone.

From a mathematical point of view, the book, as might be expected from the reputation of its authors, is very interesting and valuable. A treatise on elementary arithmetic may be criticised in two different ways, according as it is estimated in relation to pure science or to pedagogy. Most text-books on arithmetic are utterly unscientific, and a treatise like this, which aims at a rigorous method and, on the whole, achieves it, is a welcome acquisition.

The book deals with the four fundamental operations as applied to whole numbers and fractions; the metric system; elementary theory of numbers (prime factors, G.C.M. and L.C.M., recurring decimals, &c.); incommensurables, squares and square roots; ratio and proportion. Most of it is quite admirable; and the criticisms which follow are offered in no captious spirit, but as a kind of acknowledgment of the really scientific character of the book.

The authors begin by defining addition as an operation which is independent of the order of the things added; or rather they refrain from giving a definition of addition, and state that any definition must be subject to the condition above stated. Now in arithmetic it is not things, but numbers, that are added, and it is quite possible to give a satisfactory definition of an arithmetical sum. Thus take two groups of objects (in the most abstract sense), count the first group, then the second, and thirdly count the first group as before, but *go on counting* as you pass on to the second group instead of beginning again. Three numbers are thus obtained, and the third is defined to be the result of adding the second to the first. The commutative law follows easily enough.

The authors' definition of a sum is equally applicable to the addition of vectors, and this fact vitiates their statement that "a quantity A is said to be greater than another quantity B when A results from the addition of a quantity C to B."

The objection that concrete "quantities" are introduced, whereas pure arithmetic is concerned with numbers, and numbers only, applies to other parts of the book, notably to the chapter on fractions. It is quite true that concrete illustrations, such as those afforded by a two-foot rule, are very useful, and indeed indispensable for the purposes of primary instruction in the subject, but the *theory* of fractions is independent of these applications. This may be seen, for instance, in Biermann's "Theorie der analytischen Functionen" (after Weierstrass); and it is not difficult to see in Euclid's arithmetical books some foreshadowing of this way of looking at the matter.

Then, again, the treatment of irrational numbers, although greatly superior to that usually found in text-books, does not seem wholly satisfactory. The authors evidently intend to adopt the method of Dedekind, or rather, perhaps, that of Heine, but the way in which this is presented is not very clear. According to Dedekind, the existence of a single definite irrational or transcendental number is established when we are able to define a "Schnitt" in the (discrete) multiplicity of rational numbers; that is to say, when we are able to find a criterion which separates *all* rational numbers into two groups, A and B, such that every number, say a, which belongs to A, is greater than every number b which belongs to B. Thus, for instance, if we assign a rational number to A when its square exceeds 2, and to B when its square is less than 2, we establish a "Schnitt" which defines the irrational number $\sqrt{2}$. Heine's method is not very different from Dedekind's; thus his way of defining $\sqrt{2}$ consists in selecting from the groups A and B, as above defined, two sets of rational numbers:—

$$a_1,\ a_2,\ a_3\ .\ .\ .\ a_n\ .\ .\ .$$
$$b_1,\ b_2,\ b_3\ .\ .\ .\ b_n\ .\ .\ .$$

such that

$$a_1 > a_2 > a_3 > \ .\ .\ .\ > a_n > \ .\ .\ .\ (a_n^2 > 2)$$
$$b_1 < b_2 < b_3 < \ .\ .\ .\ < b_n < \ .\ .\ .\ b_n^2 < 2)$$

and then showing that if n, m are taken large enough, $a_n - b_m$ can be made as small as we please. MM. Laisant and Lemoine, after introducing the problem of measuring an incommensurable quantity, proceed: 'Jusqu' à présent on n'a rien trouvé de mieus pour remplir ce but que d'indiquer tous les nombres entiers ou fractionaires mesurant les quantités plus grandes et les quantités plus petites que A." Now, even if we waive the objection already brought forward, that the measurement of *quantities* is independent of pure arithmetic, and that the assumption that every quantity admits of arithmetical measurement in terms of an arbitrary unit requires justification (and this can only be given *after* the theory of irrational numbers has been established, if indeed then), the above statement is not satisfactory; because if A is really a concrete quantity, the "nombres entiers ou fractionaires," &c., can only mean "quantities commensurable with an assumed unit," and it remains to be proved that the choice of a unit has no influence on the result; while if A is a number, no criterion is given by which we can decide whether a given rational number is greater or less than A. On this point we cannot do better than refer to the preface to Dedekind's invaluable tract, "Was sind und was sollen die Zahlen?" in which the author expressly rejects all theories of irrational numbers based on the assumption of measurable quantities. That he is right in so doing must be admitted by all who reflect on the subject with sufficient attention.

These observations, as already remarked, are not intended to detract from the undoubted merit of the book. Arithmetic is a thorny subject, the very elements of which abound in points of great difficulty and delicacy; and any serious work on the science is certain to contain passages giving occasion for criticism or controversy. MM. Laisant and Lemoine deserve our gratitude for having

written an original and stimulating book, which should be studied, not only by professed mathematicians, but by intelligent school teachers. Such a work ought to do much towards replacing the soul-destroying routine of ordinary school arithmetic by something of a really educative character.

In conclusion, we would ask the reader to turn to the chapter on the metric system, which contains in the compass of about a dozen pages all the "commercial arithmetic" which a French schoolboy has to learn. It seems impossible that any one, after reading this chapter, can refrain from asking himself how it is that the English nation persists in refusing to adopt a system which is as easy to learn as it is convenient to use, and which, as the experience of France has sufficiently shown, could be prescribed by the State without the risk of any, save the most transient, disturbance of trade or exchange. But we are a practical people, and the metric system was invented by "theoreticians"; therefore, we suppose, nails and perches and pennyweights will be with us to the end of time.

G. B. M.

THE STRUCTURE AND LIFE OF BIRDS.

The Structure and Life of Birds. By F. W. Headley, M.A., F.Z.S., Assistant Master at Haileybury College. 8vo. Pp. xx. + 412, with seventy-eight illustrations. (London: Macmillan and Co., 1895.)

THE author in his preface intimates that "the aim of this book is an ambitious one," namely, "to give good evidence of the development of birds from reptilian ancestors. . . . and [among other subjects] to make clear the main principles of their noble accomplishment, flight." To the former of these aims Mr. Headley devotes his first five chapters, comparing the differences and resemblances observable in the skeleton and the internal structure of birds and reptiles, and the "ancestral peculiarities" that, having "survived all change of habit," mark their relationship. He then discusses the processes of life that go on within the bird, and make it so different from its lethargic reptilian ancestors, giving a description of the anatomical structure and physiological action of its chief organs. The following paragraph, from the description of the heart and circulation, will exemplify Mr. Headley's style and method of exposition:—

"The heart is a force-pump, which drives the blood to all parts of the body, and when it returns impure and loaded with used-up material, sends it to the lungs to be purified, after which it is despatched all over the body again. On the voyage much of it passes through the kidneys, which help the lungs to purge it of the waste of the tissues. The essentials of an efficient heart are that it should be strong, and that it should keep the pure blood separate from the impure. These two essentials are found combined in the hearts of mammals and birds. They are strong muscles; that part at least of them which forces the blood through the arteries is remarkable for its strong thick walls. And, thanks to the perfection of the machinery, the blood which has been purified in the lungs is never mixed with the impure blood which is coming from the body. The heart is divided into right and left chambers by a division through which there are no doorways. The right and left chambers are each divided into two, but there are openings from the upper into the lower, which may be closed by valves. The two lower chambers are called ventricles, and the two upper ones auricles."

A long chapter is next given to flight, one of the main subjects of the book; the machinery by which flight is accomplished, and the principles underlying the action of its complicated mechanism, with the extraneous aids the bird avails itself of to effect that purpose. Towards a solution of this difficult subject, on which, as the author remarks, "however much is learnt, a great deal more remains to be learned," he has contributed some original observations and experiments, for which we refer the reader to the book itself. A condensed but clear account of the bird's embryology and its subsequent life-history occupies several succeeding chapters. After this the book deals principally with colour and song, instinct and reason, migration and the principles of classification.

There is one statement made by the author, in speaking of the pneumaticity of the bird's bones, to which we feel inclined to take exception. Mr. Headley says on p. 107: "The hornbills, which according to good observers are very poor flyers, are as pneumatic [as to their bones] as any birds, or, perhaps, more so." The present writer's experience of hornbills in their native state extends to many species of several genera, among them the largest and heaviest of them all, the great solid-headed *Buceros galeatus*. Many of these birds, which may be seen—and the rush of their expansive wings can be heard long before that—constantly travelling at a great speed high over the tall virgin forests, and be watched by eye and ear for miles after they have passed over the observer, can scarcely, in his estimation, be accurately designated "poor flyers." They may not take such extended flights as birds on migration do, but they make journeys of considerable length; while in the tops of the highest trees, in quest of their food, they are quite as active and nimbly expert as those excellent flyers, the pigeons, which share with them their raids on the giant Urostigmas.

The volume before us presents little to take exception to, and it will be generally conceded that Mr. Headley has succeeded well in the aims he set before himself. He has produced a very instructive and thoroughly scientific book expressed in popular language, and one that will undoubtedly "prove useful," as he hopes it may, "to lovers of birds"; and, from the clear and concise manner in which the story of the bird's pedigree and life-history is narrated, it will be specially welcome to those of them who have not had the advantage of a scientific training in the subject; while it can scarcely fail to attract many of its readers, on the outlook for a spare-time occupation, to the study of ornithology, on which it will start them with a trustworthy groundwork.

OUR BOOK SHELF.

Fern Growing. Fifty years' Experience in Crossing and Cultivation, with a List of the most Important Varieties, and a History of the Discovery of Multiple Parentage, &c. By E. J. Lowe, F.R.S., F.L.S., &c. (London: John C. Nimmo, 1895.)

MR. LOWE'S name is so well known in connection with the production of hybrid ferns, that his book will be opened with interest by all those to whom the cultivation of these plants in any way appeals. But we must confess that the book falls somewhat short of our expectations

It is true that a very considerable space is devoted to the history of the production of hybrid forms, and that an account is given of the methods of securing successful germination of spores; but those who expect to find a treatise on the cultivation of ferns *per se*, will not find their hopes realised.

The author again takes up cudgels in defence of his views as to the existence of *multiple parentage*, a term used to express his conviction that a single oosphere can be fertilised by several antherozoids, or at the least, that a number of fertilised oospheres on one prothallium can influence the one which actually develops into a seedling plant. It is true that some of the experiments adduced by the author in support of his contention offer startling results. Thus, if a pan be sown with the spores of, say, four varieties, in a large percentage of the seedlings each will exhibit resemblances to all the four forms, instead of to only two, at most, of them. And this latitude of variation exercised in the case of a single seedling is stated to depend on the number of varieties which are sown together, and not to accidental sports.

But the inferences thus drawn by the author are so entirely at variance with the results of experimental investigations on the higher organisms, that they will meet with a cautious reception, at any rate, until the factors which make up his results have been analysed and are better understood.

Whatever the ultimate verdict which will be passed on the theoretical conclusions may be, the details of the experimental basis on which they rest, provide interesting matter enough, and suggest fresh lines of investigation which may well prove fruitful in results.

Vorlesungen aus der analytischen Geometrie der Kegelschnitte. By Sigmund Gundelfinger. Edited by Friedrich Dingeldey. 8vo. viii. + 434 pp. (Leipzig: Teubner, 1895.)

THE first part of this book (pp. 1–240) is an edition of lectures on Conics delivered by Gundelfinger within the last twenty years in the University of Tübingen and the Technical School at Darmstadt. It contains a systematic exposition of the analytical theory of Conics based on the use of general homogeneous coordinates which are so arranged that corresponding results in particular homogeneous coordinates and in ordinary Cartesian coordinates can be written down from the results obtained. It also contains an exposition of the theory of sets of Conics, including four-point and four-tangent Conics, and nets and webs of Conics. The theory is not written out with the idea of enumerating all the independent concomitant forms, but with the idea of expressing the geometrical significance of the most important ones. The appendix (pp. 240-426) contains solutions of problems on the subjects treated in the first part. Many of the problems are taken from the works of Steiner, some are original, and not a few are difficult. A very complete index is given at the end of the book.

Light. By H. P. Highton, M.A. Pp. 243. (London: Rivington, Percival, and Co., 1895.)

BOOKS upon light are many and of various qualities, but we think there is room for this little one. The subject is treated in a very elementary manner, and is made easy of comprehension by numerous diagrams. A further good point possessed by the book is that the lessons comprised in it are fully illustrated by experiments, all of which are capable of being carried out by teachers whose apparatus cupboards only contain a small stock of materials for the demonstration of optical facts and principles. The boy who goes through a course such as that described by Mr. Highton, and who sees all the experiments performed, will obtain a fair notion of the laws of light; and if he does the experiments himself, he will benefit considerably by the manual and mental training which his work will give him.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Curious Aerial or Subterranean Sounds.

IF the mysterious sounds referred to by Prof. G. H. Darwin should turn out to be of subterranean origin, as is not unlikely the case, it may be that they are the reports arising from the process of "faulting" going on on a small scale at a great depth, and not of sufficient intensity to produce a perceptible vibration at the earth's surface. In this connection I may recall an observation which bears upon the subject. When collecting materials for the report on the East Anglian earthquake of 1884, I was given a most circumstantial description of a loud report which was heard by the chief officer of the coastguard station at West Mersea during his watch between 1.10 and 1.20 a.m. on February 18 of that year. The sky was cloudless at the time, there was no flash such as might have been expected if the sound had been due to thunder or the explosion of a meteorite, and there was no artillery sufficiently within hearing to account for the sound. This report heard by the coastguard officer was afterwards found to have been *felt* as a slight shock at a house which was very much damaged by the earthquake which occurred a few weeks later (April 22), and we came to the conclusion that the officer and the inhabitant of the house in question had independently recorded a premonitory shock ("Report," p. 40, by the writer, and W. White, "Essex Field Club Special Memoirs," vol. i.). When Prof. Darwin's request for information shall have led to further knowledge as to the localities where the phenomenon has been observed, it would be of great interest to have in such places instruments for recording earth tremors. R. MELDOLA.

November 3.

Is it not possible that the "Berisàl Guns" and "mist pouffers," referred to by Prof. Darwin (p. 650), are merely earthquake sounds, the attendant shock being too slight to be otherwise perceptible? Nearly all earthquakes are accompanied by a rumbling sound, due, I believe, to the small and rapid vibrations proceeding chiefly from the margins of the area over which the fault-slip producing the earthquake takes place (*Geol. Mag.*, vol. ix., 1892, pp. 208–218). In some districts (Comrie in Perthshire, East Haddan, in Connecticut, Pignerol in Piedmont, Meleda in the Adriatic, &c.), sounds without shocks are common during intervals which may last for several years, but slight shocks with sound occasionally intervene, as if the sounds and shocks were manifestations, differing only in degree and the method in which we perceive them, of one and the same phenomenon. In great earthquakes, the sound-area is confined to the neighbourhood of the epicentre; in moderate and slight shocks the sound-area and disturbed area approximately coincide, or the sound-area may even overlap the disturbed area. In the limiting case, the disturbed area vanishes, and the vibrations are perceptible only as sound. C. DAVISON.

Birmingham, November 1.

Thermal Conductivity of Rocks.

IN view of recent discussions in NATURE anent the variation of the thermal conductivity of different kinds of rock with the temperature, the following results of an investigation, which has been in progress for the last year in the Jefferson Physical Laboratory, may be of interest.

We have made observations upon piles of comparatively large flat slabs of marble and slate by a form of "wall" method, and we hope that we have determined, with some accuracy, the internal temperature gradient.

We can detect no change in the conductivity of the block of white Carrara marble which we have used between 0° C. and 330° C.

In the case of our slate, the conductivity in a plane perpendicular to the cleavage increases about 25 or 30 per cent. between 70° C. and 300° C., the rate of increase being less rapid at the higher temperatures. B. O. PIERCE.

Cambridge, Mass., October 20. R. W. WILLSON.

MacCullagh's Theory of the Æther.

MR. BASSET'S criticisms in his letters in NATURE of October 17 (p. 595) and October 24 (p. 618) call for some reply. I willingly avail myself of the opportunity to attempt to make my meaning clearer.

(1) As regards the first letter, there seems to be some misconception. I have nowhere in the papers referred to given a proof, such as he supposes, of the theorem which he calls in question, viz. that a gyrostatic æther may be constructed which will function according to MacCullagh's optical scheme. That proposition is, I take it, Lord Kelvin's; and I simply gave references to his treatment, which occurs, at any rate implicity, near the end of the third volume of his "Collected Papers" (pp. 442, 466).

The principal aim of the second of the papers referred to (*Phil. Trans.* A, 1894) was, assuming the existence of a continuous medium with kinetic and elastic energies given by MacCullagh's expressions, to examine how far such a medium would fulfil the functions that are required of the æther, as (i.) the transmitter of radiation, (ii.) the medium in which electric actions consist and are transmitted, (iii.) the underlying medium in which ordinary matter may itself consist, in the form of permanent configurations of strain or motion possessing mobile characteristics. In MacCullagh's own time it was recognised, by none more than by himself, that a medium like his was in no way analogous to ordinary elastic matter. Moreover it was held by many that it was an impossible constitution for any medium at all. This latter conclusion I combatted by quoting the fact that Lord Kelvin has actually shown how to make a model, representing MacCullagh's medium, by means of a cellular structure composed of portions of ordinary matter in spinning motion. This is the only way that I intended to introduce the gyrostatic æther into the argument. For I hold it to be more rational to take matter to be a structure of molecular type in the primordial medium (which is not itself matter, but is a *continuum* with simpler fundamental properties than elastic solid matter) than it would be to take the æther to be a molecular or cellular structure built up out of ordinary matter.

The functions required of the æther show that it must be a medium which can have kinetic energy involving inertia, and also elastic energy of some kind when strained. According to MacCullagh's scheme, its elasticity would consist simply in resistance to absolute rotation; so that an element of volume of the medium is taken to have relations to directions in space, of the same general type as the axis of a spinning gyrostat actually possesses. The analysis of the interaction of this inertia and this elasticity forms a dynamical theory of the medium, but the dynamics is not the dynamics of ordinary matter.

Mr. Basset easily arrives at inconsistencies by applying MacCullagh's energy formula directly to the structural gyrostatic medium of Lord Kelvin. The reason is that the problem is one involving ignored coordinates (in the phraseology of Thomson and Tait's "Natural Philosophy") corresponding to the latent spinning motions of the imbedded gyrostats. Before the principle of least action can be applied after the manner of an ordinary continuous elastic medium, the actual energy function of the gyrostatic medium must be modified in the well-known manner, and it will thus assume a form equivalent to MacCullagh's. It would, no doubt, be interesting and instructive, as regards dynamical principles, to establish this in detail; but this is hardly the place to enter into a technical problem.

(2) As regards Mr. Basset's second letter, on the reflection of light from the surface of a magnet, the parallel which he draws between one type of theory which I provisionally uphold, and another which I reject, is, I think, not a real one. The latter theory retains the dynamical equations and surface conditions which belong to the luminiferous medium under ordinary circumstances, merely adding on to the electric force a new part of magneto-optic origin. This would hardly be open to objection if it worked; but it is admitted that it does not work, and in default of a specific reason being assigned for the discrepancy the theory fails. It is as if a machine, whose mode of working is thoroughly known under certain simple conditions, were observed to be working steadily under more complicated circumstances, while a mathematical analysis showed that it ought to get jammed under these new conditions. The inference would, I think, be that the machine has been reset, or some change made in its constitution, which obviated the jamming. Now the ordinary equations of the electric theory of light are, presumably, deducible from the energy function of the medium by the principle of least action. When the substance that transmits the light is in an extraneous magnetic field, there is a subsidiary term in the energy function which arises from this field; therefore the application of the principle of least action will now give different equations of the medium, and different boundary conditions, from those which ordinarily hold good. The statement that the boundary conditions which held for non-magnetic circumstances are not now maintained, is not to the point; the question is rather, whether the boundary conditions which are appropriate to the actual formulation of the problem can all be maintained, and if they can the theory is consistent.

J. LARMOR.

St. John's College, Cambridge, October 25.

Lightning.—Chain Formation.

ON September 9, 1895, I was cycling near Pitlochry, N.B. The day had been extremely hot—80° F. in the shade—and as dusk came on it grew somewhat foggy, and flashes of distant lightning became frequent. At ten o'clock there suddenly came on a terrific thunder-storm. Crash succeeded crash, and the lightning, of all colours, blazed almost continuously. Objects fifteen miles off could be seen as plainly, if not more so, than in bright daylight. The rain soon turned the road into a torrent, and my electric lamp failed to act properly. But the chief peculiarity was the occurrence of eight strange flashes of a chain formation, with large elliptical links, and of a golden-yellow colour. These flashes were not rapid in their passage, as ordinary lightning is wont to be; but one of them took slightly over a minute to pour from the clouds to the edge of the valley opposite me. Two of these chains of living, burning gold passed between adjacent clouds, while the remaining six came to earth, one in the field just beside me. I then went off to seek for shelter; but the storm continued till 1 a.m.

WILLIAM CRAWFORD.

Personal Injury from a Fire-ball.

IN compliance with a wish expressed by several scientific friends, I place on record an instance of damage done by a fire-ball or globular lightning. About five weeks ago, when I was in Londonderry, the circumstances were related to me by Mr. James Harvey, of Northland Road in that city. Mr. Harvey was staying during the month of August at Culdaff, on the north coast of Donegal; and on the 24th of that month, at about 4 p.m., a little boy named Robert Alcorn, whose parents occupied a house near Mr. Harvey's, was desired by his father to go into the yard and drive away some fowls from the door. On going out of the house, the boy saw a large bright object in the sky about the size of the table in his bedroom (I give his own account, leaving out necessary considerations of distances, &c.), or apparently about six square feet in area. The object came towards his house from the west, or north-west; and when it came close, it partly burst with a report like that of a gun. He put his hands over his face to shield himself from "the spark," and after the explosion the bulk of the ball appeared to continue its course towards the east, low down. When it burst, however, it struck him, shattering the thumb and the first and second fingers of the left hand, cutting, scratching, and blackening the right hand and left cheek, and shattering into fragments several bone buttons on his coat. Very soon afterwards, Dr. R. Young, of Culdaff, and Dr. Newell, of Moville, attended the boy, and amputated the fingers and a portion of the thumb.

No one near the place *saw* the ball (except the boy, of course), but the parents and several others heard the report, and the boy's father rushed out immediately and caught his son as he was falling. Mr. Harvey soon afterwards examined the place, and could find no further trace of the fire-ball, except that a piece of bark had been knocked off a small tree within a few feet of the place where the boy was struck. The local police made exhaustive inquiry as regards the possibility of any one's having fired a gun at the boy, or of his having had any explosive in his possession; but nothing of the kind transpired.

It is well to add that at Redcastle (about eight miles away), one of the residents saw, on the same day, a bright object in the sky, which object he took to be a fire-ball. The day was stormy, with heavy showers, but no thunder.

M. Jamin relates ("Cours de Physique," tome premier, p. 470) several instances of globular lightning, and from these I select

the following as bearing, perhaps, the greatest resemblance to the above case as regards atmospheric conditions:—

"À la suite d'un violent orage observé près de Wakefield, le 1er mars 1774, lorsqu'il ne restait plus dans tout le ciel que deux nuages peu élevés au-dessus de l'horizon, M. Nicholson voyait à chaque instant des météores semblables à des étoiles filantes descendre du nuage supérieur au nuage inférieur."

October 28. GEORGE M. MINCHIN.

The Dispersal of Acorns by Rooks.

IN peat-mosses, on open chalk downs, and in ploughed fields, often a mile or more from the nearest mature tree, one constantly finds acorn-husks and also seedling oaks, which last a few months or, perhaps, a couple of years, and then die, the conditions being unfavourable. It has always seemed to me, while studying the origin of the existing fauna and flora of Britain, that this dispersal of acorns ought to give an important clue to the means by which this country was again clothed when the climate became more genial after the Glacial Epoch. The oak has the largest seed of any British plant, and if it can be carried distances of a mile or more, it is evident that the whole of our present flora may have spread more rapidly than is usually imagined, and may have crossed straits and wide rivers.

I have for several years noted the position of these seedling oaks, finding them in places where no mammal would take the acorns. For instance, they are common in any of the New Forest peat-bogs that are within a mile of an oak-tree. They are common also in some places on the top of the escarpment of the South Downs, half a mile from oaks, and 300 or 400 feet above them. They are always associated with empty acorn-husks, stabbed and torn in a peculiar way.

In October and November rooks feed in the oak-trees, and I have long felt convinced that they were mainly responsible for the dispersal of acorns, though it is not easy to catch them actually doing it. On October 29 of this year I was successful. In the middle of an extensive field, bordered by an oak-copse and scattered trees, a flock of rooks was feeding and passing singly backwards and forwards to the oaks. On driving the birds away, and walking to the middle of the field, I found hundreds of empty acorn-husks, and a number of half-eaten pecked acorns, which had not had time to change their colour—a cut acorn changes colour on exposure to the air like a cut apple, though not quite so fast. This showed that the birds had been disturbed in the middle of their feast, for the marks on the acorns were quite unlike those made by a rodent or any mammal. They were stabbed and pecked, and the husks were torn off in strips, usually starting from a puncture. It was also noticeable that many of them were not shed acorns, but were accompanied by acorn-cups, the stalks of which had been bitten to tear them off the trees. This was singular, for the ground beneath the trees was covered with shed acorns. The rooks, however, were in the trees, not under them, and the reason for the selection of acorns in cups is probably that they are easier to carry—a shed acorn must be an awkwardly large and slippery thing for a rook's beak, one with a stalk will be more convenient. Several uninjured acorns were found, and most of the remains occurred on smooth spots of short turf—places where a slippery acorn might conveniently be pecked without being lost. One almost uninjured acorn had been driven by a single peck deep into the soft soil of a mole-hill.

It might be thought that it would be much simpler for the rooks to feed on the ground beneath the trees. Some of them apparently do so; but the majority seem always to carry the acorns into the open. The rook is a suspicious bird, quarrelsome, and a born thief. He seems particularly to object to a comrade watching him from any post of vantage, and the rooks when among the oaks, for some reason or other are always quarrelling, notwithstanding the abundance of food. An acorn dropped on rough ground or in a peat-moss would stand a great chance of being lost in some crevice or soft place; but the oak seeds so freely, that the bird need not waste time trying to recover the lost acorn—there are plenty more on the tree.

In this way oak-woods must spread rapidly. But we still want observations as to the distance to which acorns can be carried. I have seen seedling oaks at a distance of a mile from the nearest mature tree (not necessarily the tree from which the acorn came), and have found the characteristically torn husks somewhat further away. Do rooks roosting in elm-trees ever carry home acorns for supper? There used to be a number of rooks which roosted in elms near Brighton in the autumn and winter, but crossed the Downs to feed in the Weald. I have often watched them returning at dusk. Do they ever bring acorns from that distance? This flock may have been responsible for the seedling oaks near the edge of the Downs; and if it could occasionally bring an acorn still further, to Brighton, it is evident that the oak may have crossed the Strait of Dover, when it was somewhat narrower, and that Britain, as far as the oak shows, may have been continuously an island since the Glacial Epoch. CLEMENT REID.

On the Audibility of Fog Signals at Sea.

IN NATURE of August 8, attention was called to some recent investigations, published in *Hansa*, on the inaudibility of fog-horns at sea within certain zones surrounding the signal, although the horn is distinctly heard outside of such regions. It seems strange to me that I can find nowhere suggested that this may be a phenomenon of interference similar to that suggested in light by Dr. Lloyd of Dublin (*Trans. Roy. Irish Acad.*, vol. xvii.).

If we let x equal the distance of the observer from the signal, h and y the heights of the signal and the observer, respectively, above the level of the sea, and δ the linear difference between the paths of the reflected and the direct rays of sound, then

$$x = \frac{1}{2\delta}\left\{\delta^4 - 4\delta^2\,(y^2 + h^2) + 16\,h^2y^2\right\}^{\frac{1}{2}} = \frac{2\,hy}{\delta}$$

approximately. An attempt to apply this formula to the observations recorded in the Report of the American Light-House Board, published in 1894, was foiled by the lack of sufficient data for substitution in the above formula. However, if $h = 100$ ft., $y = 30$ ft., and δ be taken for a wave-length of 2 ft. (which are probable values for the variables), then we would expect minima of sound at 1·1 and 1/3 miles, the maximum between these being at a distance of half a mile from the source of sound, which quantities are of the right order of magnitude. These distances might be modified considerably by refraction, the wind, and to some extent by the tide. When there are two minima, as in the *Hansa* experiments, this seems a much more probable explanation than that by refraction alone generally offered, and it explains the phenomenal loudness outside the silent area. The above equation shows that the boundaries of the silent regions in vertical planes are hyperbolas, which is essentially different from what the refraction theory gives. F. E. FOWLE.

Washington D.C., U.S.A., October 21.

To Friends and Fellow Workers in Quaternions.

IN NATURE for October 3, 1895, there is a letter, signed by P. Molenbroek and Shunkichi Kimura, on promoting the study of quaternions and allied systems of mathematics. I notice that this has not, as yet, been responded to in NATURE. I do not think that the subject should be allowed to drop; but that some permanent good should be done to science by making this branch of mathematics part of the compulsory course of study for students for the highest honours in mathematics in our universities and uuniversity colleges, in the hope that more workers may follow the subject up afterwards.

Unquestionably the calculus is of very great value in the higher natural philosophy, and in every sense will repay the trouble bestowed upon it, though I speak in all meekness and not as an eminent authority on the subject. May we hope for some information as to what form the literature of the International Association will take? G. H. J. HURST.

Eton College, Windsor.

The Colours of Mother-o'-Pearl.

HAD Mr. C. E. Benham given his address when writing to you on this subject (NATURE, vol. lii. p. 619), I should merely have taken the liberty of sending to him direct a copy of a paper entitled, "Prof. Blake and Shell-growth in Cephalopoda" (*Ann. and Mag. Nat. Hist.*, ser. 6, vol. i. pp. 421–427, June 1888), in which similar arguments to those of Mr. Benham were adduced. Now, however, perhaps you will permit me to refer Mr. Benham to Dr. W. B. Carpenter's report on shell-structure (*Brit. Assoc. Rep.*, 1844, p. 11). As for the text-book writers, who usually support their explanation of the iridescence of mother-o'-pearl by reference to the theory of

Brewster, they may be recommended to study his original paper (*Phil. Trans.*, 1814, p. 397), when they will see that such a reading of it is both incorrect and incomplete.

F. A. Bather.

Natural History Museum, October 28.

THE STAR SHOWERS OF NOVEMBER.

Well may Mr. Greg, in his catalogue of meteoric radiants, published in 1876, affix a remark indicating the all-surpassing character of the mid-November meteors. For if there is one star shower more striking than all the rest, it is assuredly the Leonids. Every one who has seen the phenomenon at its best, is prepared to admit that it furnishes a grander spectacle than any other system, and will have realised that, once seen, it impresses itself indelibly upon the memory. There can be very few people living now who witnessed the great shower in America on the morning of November 14, 1833, but there are many Englishmen who vividly remember the fine but less splendid exhibition of 1866. With a swiftness unsurpassed among meteor streams, and with a brilliancy quite their own, the Leonids belong to the most striking class of these bodies, and offer a great distinction to the slow and gentle flights of the Andromedes, or meteors of Biela's comet which present themselves about a fortnight later. It is true the Leonids are only manifested, in vast abundance, once in a generation, and that, considered as an annual display, they usually fall below the strength of the August Perseids. But, considering all things, the November shower is undoubtedly entitled to precedence. The writer saw the Leonids in 1866, he also observed the rich displays of Andromedes in 1872 and 1885, and has been fortunate enough to witness many bright returns of the Perseids and of other prominent systems; but, of all such spectacles, one only, by its surpassing splendour, created an impression which still lives fresh in the memory, and that was the Leonids of November 1866.

The similar display which occurred in 1833, may be regarded as a very auspicious event, since it attracted attention to an important branch of astronomy which had been systematically neglected. Men began to seriously regard a phenomenon capable of giving such a remarkable sky picture, and the facts relating to it were collected and discussed. But the meteor showers of 1833 and 1799 were understood to be very exceptional events, and they had not been observed with that attentive regard to details which is so essential in this class of observation. Astronomers, however, were led to suppose that historical records might contain references to similar phenomena witnessed in ancient times, and Herrick, Quetelet, Arago and others, on consulting old works, found a number of descriptions of star-showers preceding that of 1799, and obviously of the same character. These occurred in 902, 931, 934, 1002, 1101, 1202, 1366, 1533, 1602, and 1698. A list of the dates was given by Prof. Newton in the *American Journal of Science* for May 1864, and he found, on comparing the intervals separating the various returns, that these brilliant meteoric apparitions visited us four times in every 133 years. The descriptions of them were quaint and imperfect, and of little scientific value apart from affording an important clue as to the period of the swarm; but it may be interesting to quote from a few of them. In October 902, a vast concourse of falling stars were scattered over the sky as thick as rain. On October 19, 1202, "stars shot hither and thither in the heavens eastward and westward, and flew against one another like a swarm of locusts; this phenomenon lasted until day-break; people were thrown into consternation and cried to God the Most High with confused clamour." A Portuguese chronicle thus refers to the shower of 1366: "Twenty-two days of the month of October being past, three months before the death of the king Don Pedro of Portugal, there was in the heavens a movement of the stars such as men never before saw or heard of. At midnight, and for some time after, all the stars moved from the east to the west, and after being collected together they began to move, some in one direction, and others in another. And afterwards they fell from the sky in such numbers and so thickly together that as they descended low in the air they seemed large and fiery, and the sky and air seemed to be in flames, and even the earth appeared as if ready to take fire." Coming down to modern displays, Humboldt saw thousands of bolides and falling stars succeed each other during four hours on the morning of November 13, 1799. The phenomenon returned in 1831 and following years, and the facts may be referred to seriatim:—

1831 November 13 a.m. An account of this shower was given to M. Arago by one of the officers of the French brig *Loiret*, as follows: "The sky being perfectly cloudless, and a copious dew falling, we have seen a number of shooting stars and luminous meteors of great dimensions. During upwards of three hours two per minute were seen. One of these meteors which appeared in the zenith left an immense train from east to west, like a luminous band, and the light it gave did not disappear for six minutes."

1832 November 13 a.m. Capt. Hammond, of the ship *Restitution*, then in the Red Sea, off Mocha, says: "From 1 a.m. until daylight there was a very unusual phenomenon in the heavens. It appeared like meteors bursting in every direction. On landing in the morning I inquired of the Arabs if they had noticed the above. They said they had been observing it most of the night, but had never seen the like before."

1833 November 13 a.m. The phenomenon continued during seven hours. At Boston the number of meteors was considered to equal one-half of the flakes which filled the air in an ordinary fall of snow. The number visible was estimated as upwards of 240,000. Another observer stated that between 4 and 6 a.m. about 1000 meteors per minute might have been counted.

1834 November 13 a.m. A large number of shooting stars seen in the United States.

1835 and 1836. Many meteors observed on same date. In the latter year, on November 13 a.m., an immense number of meteors made their appearance between midnight and daylight, but the display did not equal the shower of 1833.

1864 November 13 a.m. An observer on board the steamship *Ellora*, off Malta, wrote on November 14 as follows: "There was a grand display of meteors from midnight to 4h. a.m., all through the watch, the night before last. The watch, an old 'salt' and an intelligent man, said that it was the grandest shower he had ever seen." None were visible on the morning of November 14.

1865 November 13 a.m. Between 1h. and 5h. a.m. 279 meteors were seen by six observers at Greenwich, and it was computed that the total number visible during that period must have been fully 1000. Prof. Herschel noted 71 meteors between midnight and 3 a.m. At Cambridge University 98 meteors were observed between midnight and 2 a.m.

1866 November 14 a.m. 8485 meteors were counted by several observers at Greenwich. Mr. Wood, at Birmingham, estimated that between 1h. and 1h. 30m. a.m. meteors appeared at the rate of 3600 per hour. The maximum occurred at about 1h. 10m. a.m. when Dr. Burder, of Bristol, counted 80 per minute. From the combined observations of several persons looking in different directions, Mr. Lawton, of Hull, made the number of meteors to have been 144 per minute for nineteen minutes from 12h. 58m. to 1h. 17m. a.m.

1867 November 14 a.m. Weather generally unfavourable in England. At St. George, Grenada, there "was observed before day-break a shower of luminous meteors flying about in every direction and of every conceivable magnitude." At the University Observatory, Toronto, four observers counted 2287 meteors between midnight and 6 a.m. Of these 1345 were seen during the hour from 4 to 5 a.m.

1868 November 14 a.m. Many meteors seen in England, but the sky much overcast. At Rome, Secchi reported that 2204 meteors were counted between 2.30 a.m. and 5.45 a.m. At Toronto, Canada, 2886 meteors appeared between November 13 10h. 45m. p.m. and November 14 5h. a.m.

1869 November 14 a.m. Lieut.-Colonel Tupman, at Port Saïd, Lower Egypt, counted 136 meteors between 2.30 and 5h. 14m. a.m., and they were nearly all Leonids. At Santa Barbara, California, 556 meteors were noted by two observers in 2h. 25m. before 3h. 43m. a.m.

In 1870 moonlight partly interfered, but it was evident the meteor shower had lost its conspicuous character—a fact fully confirmed by observations in 1871. But it had not entirely disappeared, for in the years mentioned, and in those which succeeded, the middle of November always brought some of the swift streak-leaving meteors from the well-known radiant in the sickle of Leo.

In 1879 and 1888, on the morning of November 14, very distinct showers of Leonids were observed by the writer at Bristol, and in many other years they were also visible. Mr. Corder, at Bridgwater, saw a few Leonids in 1892, and, in 1893, Prof. Barnard, in California, described them as far more abundant than he had ever seen them before. Many very brilliant ones were seen, and they were especially plentiful on the mornings of November 13, 14 and 15. In 1894 moonlight interfered with observations.

This meteor system evidently forms a complete ellipse, for there seems no reason to doubt that it returns annually without a break. Even in parts of the orbit very far removed from the dense cluster, which seems identical with Tempel's comet (I. 1866), the meteoric particles appear to be pretty numerously distributed, for there were fairly active displays in 1879 and 1888. It is true the shower has not been observed every year, but there is good reason to assume its annual recurrence, and that it would be seen were the nocturnal sky free from clouds and moonlight just at the critical time.

One of the most important features of a meteor shower is that the flights are directed from a common centre, and no observation of such a shower can be regarded as complete unless the radiant point has been determined. The writer has generally found the radiant of the Leonids very sharply defined, and it admits of being accurately detected even by observers who are inexperienced, for the meteors leave luminous streaks, and these, lingering for one or two seconds, enable the directions to be correctly registered. The Leonid radiant has been frequently obtained, and the following are some of the values given by different observers in various years.

1833	November	13 a.m.	148°	+24°	Aiken.
,,	,,	,, ...	150	+20	Olmsted.
1836	,,	,, ...	150	+20	G.O.S. New York.
1865	,,	,, ...	148	+23	A. S. Herschel.
,,	,,	,, ...	148	+23	Newton.
,,	,,	,, ...	148	+24	Marsh.
1866	,,	14 ...	149	+23	Mean of nineteen positions by the best observers.
1867	,,	,, ...	147¾	+23	Bradley.
,,	,,	,, ...	150¾	+22	Watson.
,,	,,	,, ...	148	+23	Harkness.
,,	,,	,, ...	150¼	+22½	Sands.
1868	,,	,, ...	152	+18	Gilman.
1869	,,	,, ...	151	+22	Tupman.
1877	,,	,, ...	146	+26	Backhouse.
,,	,,	11–14 ...	148	+24	Denning.
1879	,,	14–16 ...	147	+23	Perry.
,,	,,	16 ...	151	+22	Sawyer.
,,	,,	12–14 ...	148	+25	Corder.
,,	,,	14 ...	148	+23	Denning.
1880	,,	12–13 ...	148	+22	Sawyer.
1885	,,	15–18 ...	150	+22	Denning.
1887	,,	15 ...	155	+25	Booth.
,,	,,	15 ...	150	+22	Denning.
1888	,,	14 ...	149	+22	Denning.
1890	,,	14–15 ...	151	+24	Backhouse.

In addition to these, some good positions are given in the catalogues of radiants by various authorities, thus:—

November	10–14 ...	148°	+22°	Schmidt.
,,	7–15 ...	153	+22	Greg and Herschel (1863.)
,,	12–13 ...	148	+24	Heis.
,,	11–15 ...	149	+23	Greg (1876).

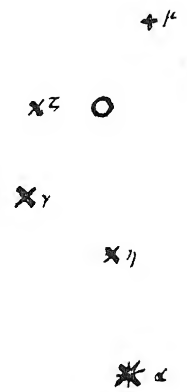
The mean place derived from a large number of positions, agreeing well amongst themselves and individually fixed by the most trustworthy observers, is at

$$149^{\circ}{\cdot}15 + 22^{\circ}{\cdot}9$$

This is almost identical with that of the naked eye star Piazzi IX. 230 (mag. 5·7). the place of which in 1880 was

$$149^{\circ}{\cdot}1 + 22^{\circ}{\cdot}5$$

Relatively to the bright stars forming the sickle of Leo the radiant is situated as in the following diagram:—



Place of the Leonid Radiant amongst the Stars in the Sickle of Leo.

It is of no utility beginning a watch for Leonids before 10.30 p.m., as the radiant does not rise until about that time. It is very rarely that a meteor is seen from a radiant on or a little below the horizon, but a remarkable Leonid was observed in 1879 November 13, as early as 10h. 20m. at three different places, viz. Writtle, Bedford and Bristol. As seen from the latter place, the meteor passed through an arc of 90°, the observed path being from 98° + 22° to 4° − 15°.

The interest in this meteor shower is now rapidly increasing, for we are drawing near the period when brilliant returns may be expected. Two years preceding the maximum, as in 1831 and 1864, we may certainly look for rich displays, so that November 1897 will form an important epoch. It is also in the highest degree probable that in 1895 and 1896 the shower will give decided indications of returning activity. This year the conditions will be very favourable, as the moon, being a slender crescent and within a few days of the new, will be unable to make her influence felt.

The shower of Leonids certainly endures from November 9 to 17, but the really brilliant displays only last a few hours, and these at the end of the present century will occur either on the mornings of the 14th or 15th. 1896 being leap year, the phenomenon may be expected earlier than usual. The year 1898 offers prospective events of extraordinary interest to the meteoric observer, for two brilliant displays may occur within ten days of each other. The Leonids will be due on November 14, and the Andromedes on November 23.

As to the nature of the observations necessary during the progress of a meteor shower, it may be suggested that two persons are required to fully note the features presented. One will record the number of meteors appearing during short intervals, say of five minutes, so

that the time of maximum may be ascertained as well as the aggregate number visible during the period covered by the watch. The other will register the individual paths of well-observed meteors on a star chart or celestial globe, determine the place of the radiant and its character, especially note large meteors and any other peculiarities that may offer themselves. One observer, working single-handed, may do a great deal by dividing his attention between the various points alluded to. It is always important to separate the number of meteors visible in a special shower from the total number seen, for the aggregate counted must exceed the actual strength of a particular stream, since it includes the sporadic meteors. When reckoning the visible meteors, therefore, the observer will do well to keep an account of the number unconformable with the radiant of the main display. The radiant of the Leonids can be readily assigned, not only because of the afterflows or phosphorescent streaks left by the meteors, which assist the eye in fixing their exact directions, but also on account of the well-known asterism involving it. The Leonids exhibit a more contracted area of radiation than the Andromedes, but it is a feature not yet thoroughly investigated. By selecting a number of well-observed tracks near the radiant, the extent of its diffusion may be readily determined. The writer has sometimes found the centre so definite that the conformable paths have intersected at a point.

W. F. DENNING.

THE OLD AND NEW NATURALISTS.

NATURALISTS, like the animals and plants of which they discourse, are subject to the process of evolution. The naturalist of the latter end of the nineteenth century is not quite the same species as that which bore the name at the end of the eighteenth. Differentiation has been at work. So markedly indeed is this the case, that one is tempted to ask whether the species, as such, is not well-nigh extinct. To-day there are biologists, comparative anatomists and physiologists, systematic botanists and systematic zoologists, palæontologists and embryologists. But where is the naturalist? Has he not been swallowed up by and distributed among his polyological progeny? And yet the word is still in use, and carries with it a more or less specialised implication. The other day a friend, who was discussing with me the work of an acquaintance, said: "He's a capital anatomist; it's a pity he's not more of a naturalist"; and I had no difficulty in catching his meaning. It may be worth while to consider the relative position and status of the old and of the new naturalist.

In one of his luminous essays—that on the study of biology—Prof. Huxley reminds us that Hobbes of Malmesbury (Leviathan Hobbes) said: "The register of knowledge of fact is called history. Whereof there be two sorts, one called natural history; which is the history of such facts or effects of nature as have no dependence on man's will; such as are the history of metals, plants, animals, regions, and the like. The other is civil history; which is the history of the voluntary actions of men in commonwealths." In Hobbes's terminology, then, naturalist was synonymous with man of science. Indeed, until quite a recent date, as I am told, the Professor of Zoology in one of our northern universities bore as his technical title the designation Professor of Natural and Civil History. Gradually the field of the naturalist was restricted. Those branches of science which seemed to be specially susceptible of mathematical treatment were allotted to the natural philosopher; the naturalist, as such, continued to deal with physical geography, geology, mineralogy, and the history of plants and animals. The names of Buffon and of Humboldt at once rise to our minds as those of naturalists of this encyclopædic type. But the progress of knowledge, and the vast accumulation of facts, necessitated further division of labour; and by this further differentiation the field of the naturalist was yet further limited to the natural history of animals and of plants. Nor did the process of differentiation stop here. To-day we have herpetologists and ichthyologists; we have zootomists and embryologists; we have systematic botanists and evolutionists; but where, one may again ask, is the naturalist?

I take it that the term "naturalist," as we now use it, implies the sympathetic study of animals and plants in their varied relations to each other under the natural conditions of their customary habitat. In short the naturalist is in great part what Prof. Ray Lankester would call a student of bionomics, or what Semper called an investigator of the higher physiology of organisms. His calling is a protest, first, against the wide-spread error that physiology ends with the individual; and secondly, against the no less erroneous view that science ends with analysis. The naturalist sees in the individual animal or plant merely a constituent unit in a connected whole; and welcomes the most minute analysis chiefly as a means to a more complete synthesis.

Looking back to naturalists of the past in the light of this conception, it is of Gilbert White of Selborne that we feel the term to be exactly descriptive; and in the old days it was the man of leisure like White, the sportsman like St. John, or the angler like Izaak Walton, that was the best and most characteristic naturalist. They started with no equipment of special training, indeed, but with a keen eye, an observant habit, and a generous love of all that ran wild and all that grew free in the face of heaven. They gave their hearts to nature for its own sake; their lavish interest therein had no ulterior motive; they accepted the plain unvarnished tale of creation, and were troubled by no problems of evolution, and in their writings their main object was close, accurate, and sympathetic description rather than reasoned and logical explanation.

Nor can we read the works of the older naturalists without feeling that they were humanists as well. It is true that the more typical humanists of their time regarded their naturalist proclivities in the light of amiable eccentricities, as hobbies with little or no intimate bearing on man, the central figure in all rational and serious study and investigation; little dreaming of the influence natural history was destined to exercise in their own proper sphere of work. But the naturalists were wiser than they knew; wiser perhaps than some modern humanists on the one hand, and some modern naturalists on the other. They included man in their field of view.

Is it too much to say that the connecting link between the old and the new naturalists is to be found in Charles Darwin? The author of the "Naturalist's Voyage" had received but little systematic training, as we now count systematic training; he had the keen eye and the observant habit; he had the generous love for, and sympathy with, nature in all her aspects; he was indeed an encyclopædist in his width of interests, which included physical geography and geology as well as the world of plants and animals; and man was assuredly not absent from his field of view. Is any one likely to question the assertion that Charles Darwin was a great naturalist of the old type? And after more than twenty years of experimenting, investigating, collecting an enormous mass of data, and thinking of the careful patient type which brilliant little bodies even now fail to appreciate, he gave to the world his "Origin of Species," by which the work of all future naturalists was set in a new light. And after that, did he not write his "Orchids," his "Insectivorous Plants," his "Climbing Plants," his "Earthworms," all of them full of the spirit of the new natural history? Had Darwin made another voyage, and had he given us another journal of a naturalist, what we should have

looked for would have been a new description of the animal and vegetable world in their natural relations under the observed conditions of their life, interpreted in the light of the new principles which he himself had gone so far to establish. And this, as it seems to me, marks out the field of work of the naturalist of to-day and to-morrow. He must have grasped the nature of the great biological problems which the latter half of this century has opened up; he must retain the keenness of eye and quickness of observation which characterised the older naturalists; he must deal chiefly in accurate and graphic description, and not too much indulge in speculation—keeping his more speculative work for other modes of presentation; but he must also be to us the interpreter of the facts of animal and vegetable life *as it is lived in the open face of nature*, in terms of recognised principles of biology, and yet wholly without prejudice, forcing no dogma upon nature, expecting daily to discover new truths, and aware of the provisional character of so many of the conclusions of the evolutionist.

If then we attempt to define the naturalist, we may say: first, that his subject-matter is animate nature as it is; the inter-relations of living things in the web of life, the bionomics or higher physiology of organisms. Secondly, that his method is primarily observational; but that, if the synthetic picture is to be achieved, he must be aware to the full of the results of analysis in physiology, psychology, and ætiology. And thirdly, that his mood must be sympathetic, and that to be successful in his presentation he must combine the qualities, not only of the man of science, but also of the artist.

While much admirable and fascinating work has been done by traveller-naturalists in many parts of the world, it must be remembered that there is abundant work for the stay-at-home naturalists in the ponds and hedgerows, woods and shores, of our own country. The members of our field-clubs may do excellent service to the general cause of natural history. But, without denying the value of cataloguing the local faunas and floras, we must recognise that many field-clubs and naturalists' societies err in confining themselves too exclusively to this. Precise observations as to the habits of animals, and the environmental relations are needed even more urgently than systematic work of this kind.

And here a word or two may be said on "Natural Histories." Most of the natural histories of animals have not sufficiently shaken themselves free from the bondage of the systematist. They are to a large extent hybrid works with a foundation of more or less popularly expressed systematic zoology, and sections or paragraphs on habit and instinct. Brehm's "Tierleben" is, however, a treasure-house of observations as to the life and habits of animals to which Darwin and many others have freely acknowledged their indebtedness, while others have not. The "natural history," as such, should have for its primary subject the inter-relation of animals and plants, the web of life as it is presented to our study; and to this all reference to anatomical structure, systematic position, and individual habit, should be made subsidiary. In botany, Kerner's great work, a translation of which by Prof. Oliver is now published, affords an admirable example of what a natural history should be. The bionomic note is here distinctly dominant.

Of course under the new conditions of the present time the preliminary training of the naturalist needs to be both wider and fuller than was either possible or necessary for the older naturalists. He must be not only well read in, but must have real practical acquaintance with, physiological and biological investigation. There is, moreover, one point in connection with the preliminary training of the naturalist which appears to me to be important. In his description of animal life he will have to interpret many of their actions in terms of the underlying mental processes. To do this with any success he should have a training in psychological methods. Such training has been too much neglected in the naturalists of the past; and even now it is often assumed, or so it would seem, that whereas when biological problems are concerned, the guidance of untrained mother-wit is, by itself, scarcely adequate, yet, when psychological problems are concerned, this is amply sufficient.

That his work may be effectual, the naturalist should be not only a man of science but a man of letters. This will give to his interpretation a special value. But he must be both in equal degree. He must not, as is too often the case with magazine writers, regard natural history as merely a subject on which may be written a certain number of bright and pleasing pages which shall not require any undue amount of exercise of thought on the part of his readers. Not that in saying this I would utter one word in disparagement of such writers as Kingsley, Jefferies, and Burroughs, of Mr. Warde Fowler, and a number of keen observers who have made their observations the subjects of delightful essays. Nay, rather I would contend that these writers have done good service in illustrating the value of the sympathetic mood, in emphasising a healthy reaction against "mere necrology," in vindicating the right of the amateur to contribute towards the end all naturalists have in view. But I still feel that, for the naturalist as such, his first and foremost object must not be to give us pleasure by his manner and method, by his delicacy of touch and his imaginative treatment; it must rather be to tell us something which in and for itself is worth knowing, since it will give us a deeper and truer insight into the world of living things. Literary finish, grace of style, imagination and graphic power should be there; but this should be like the cutting and polishing of the gem which, though it enhances its value, does not by any means constitute the chief element thereof.

The species naturalist, then, is not dead but liveth. It includes not only the professional, but the so-called amateur. The naturalist has been of late in La Plata, in Borneo, in Celebes; he has told us of the wonders of animal life on the ocean surface; he has watched the struggle for existence in a tropical forest and on the sea-shore; he is at work among aquatic insects, and learns the ways of birds and insects on Bindon Hill; he knows not only the zoology but the natural history of rotifers, and can discourse delightfully to the Royal Microscopical Society on the unnecessary difficulties in the way of studying natural history; and he still looks out across the waters of Poole Harbour to Corfe Castle, and tells us of the days of his youth in the Malay Archipelago.

In conclusion we may say that just as the early poets were frankly and naïvely descriptive, so too were the early naturalists. Neither dealt in deep and subtle analysis. But the time of analysis came and flooded the world. The modern poet profits by all this analysis, is indeed a subtle analyst himself; but, as poet, he keeps his analysis out of sight, and gives us a new presentation of nature in descriptive and synthetic form. So too must the modern naturalist profit to the full by all the biological and psychological analysis of his times; but, as naturalist, he must keep all this out of sight, and give us a new presentation of animal and vegetable life in descriptive and synthetic form. And he must remember that his picture will not be complete unless it include man himself. For man is also in the web of life, influencing and being influenced by all around him; nowise to be ignored, but to be taken account of to-day as he was by Humboldt, and by the stronger naturalists of the old school. And this new descriptive presentation of nature, as it reveals itself to the eye and brain of the modern naturalist, will differ chiefly from that of his predecessor, first, in that it is no longer a piece of amiable eccentricity, but is in close touch with the

gravest problems that man has to grapple with; and secondly, in that it has more or less distinct reference to a past of which the present is but an outcome and a development. C. LLOYD MORGAN.

HERMANN HELLRIEGEL

PROF. HERMANN HELLRIEGEL, whose death took place at Bernburg, Anhalt, on September 24 last, was born at Pegau, Saxony, on October 21, 1831, so that he was within a month of completing his sixty-fourth year. His life, on the whole, was uneventful, for he devoted himself with studious zeal almost entirely to investigations, both chemical and physiological, into the phenomena of plant nutrition. One of his earliest official posts was that of Director of the Agricultural Experiment Station at Dahme, in Brandenburg, which was founded in 1857 by an association of agriculturists in Jüterbog-Rückenwalder. During his tenure of this post he studied experimentally the alimentary needs of certain plants which are cultivated as field crops, notably cereals, potatoes, and sugar-beet, his method involving the use of sterilised soil, both by itself and with the addition of various chemical salts. His physiological inquiries embraced observations on the growth and development of roots, on the quantity of water used in the growth and maturation of field crops, and on the minimum amounts of nitrogen, phosphoric acid, potash, and other ingredients required by plants. Supplemented by observations on crops grown in the open field, these investigations led Hellriegel to conclusions of great practical importance, notably in connection with sugar-beet, a crop which Germany grows more extensively than any other European country, its annual average area for the last twelve years having been 800,000 acres, or more than one-fourth of the entire European acreage.

It was with no little regret that in 1873 Hellriegel gave up his directorship at Dahme, though for a post with greater emoluments. But his capacity as an investigator had made its mark, and when in 1882 the Verein für Zucker-Industrie, in co-operation with the Government of the Duchy of Anhalt, established an experimental station at Bernburg, for the special investigation of problems bearing upon the cultivation of sugar-beet, it was felt that Hellriegel possessed special and peculiar claims to the directorship, which was accordingly offered to him. He accepted with avidity a post which enabled him again to devote his time and energy solely to those investigations into plant-life, which had previously exercised upon him so strong a fascination. The station at Bernburg is admirably equipped, and Hellriegel found himself in a position to at once resume his inquiries into the nutrition of leguminous plants, a subject that had previously received his attention at Dahme. It was here that after a dozen years' work he, in collaboration with Dr. Wilfarth, made the great discovery with which his name will ever be inseparably associated, namely, the capacity of leguminous (or at least of papilionaceous) plants to take up, or fix, through the agency of the micro-organisms of their root-nodules, the free or uncombined nitrogen of the atmosphere.

The intimation—the revolutionary announcement—of this startling discovery was made on September 20, 1886, in a communication to the Naturforscher Versammlung, held at Berlin, and over the agricultural chemistry section of which Dr. (now Sir Henry) Gilbert happened to be presiding—a coincidence of exceptional interest in view of the circumstance that Sir Henry Gilbert was one of the joint authors of the celebrated memoir by Lawes, Gilbert, and Pugh, "On the sources of the nitrogen of vegetation, with special reference to the question whether plants assimilate free or uncombined nitrogen" (*Phil. Trans.* 1861), which, at the time of its appearance, and for long after, was regarded as setting at rest the question as to the capacity of plants to assimilate the free nitrogen of the atmosphere, and of confirming upon this point the negative results previously obtained by Boussingault. Hellriegel's momentous discovery furnished an explanation of the long-known fact that a clover-crop leaves the soil richer in nitrogen than it finds it, and is therefore a suitable crop to precede the wheat-crop in a rotation, clover being—as we now understand through Hellriegel's discovery—a nitrogen-accumulating plant, and wheat a nitrogen-consuming one. Indeed, the fact itself is a very old one, for it was observed by the farmers of the Roman Republic that beans, lupins, vetches, and other plants belonging to the sub-order Papilionaceæ, as now defined, rendered the soil "more fruitful" for the crops that followed. But nearly 2000 years elapsed from the time when Varro recorded this, to that when Hellriegel, a brief nine years ago, supplied the explanation. It in no way detracts from the value and significance of the discovery that Hellriegel and Wilfarth should have happened upon it in the course of investigations which were really directed to quite a different object. Those who devote their lives to research are not unaware that gems, hitherto unseen, may sometimes be picked up on the wayside.

We have spoken of Hellriegel's discovery as revolutionary, and it certainly upset a long-cherished belief. The opposition which his announcement received at the outset was a testimony to its importance. Subsequent research, both in Europe and in North America, has, however, only strengthened the position which Hellriegel took up, whilst it has suggested new lines of investigation for which there will probably be no lack of workers. Bréal, Frank, Hiltner, Lawes and Gilbert, Schlœsing fils and Laurent, are but a few of the investigators who have proved the accuracy of the discovery made at Bernburg. In recognition of his work, Hellriegel was elected an honorary member of the Royal Agricultural Society of England, a rare distinction, which he enjoyed in common with such continental workers as Pasteur, Fleischmann, and Chauveau. In France his merits were recognised by his election as a foreign associate of the Société nationale d'Agriculture, and as a Correspondant of the Academy of Sciences.

NOTES.

THE German committee for the exploration of the South Polar regions met at Berlin on Sunday, and decided to send two vessels southwards from Kerguelen Island, leaving full liberty of action to the leaders. The total sum to be allotted for the expedition, which is to last three years, has been fixed at 950,000 marks (£47,500).

CHICAGO UNIVERSITY continues to be the recipient of Fortune's favours. Mr. John D. Rockefeller has (says the New York correspondent of the *Daily Chronicle*) added £200,000 to his previous gift of £800,000 for the endowment of the Chicago University. He promises £400,000 more if any one else will subscribe a like sum. When will the day come for such generous gifts to education and research in England?

THE Municipal Council of Arbois, the birthplace of Pasteur, has decided to erect a statue to his memory, and also to call the municipal college the Pasteur College.

M. BERTHELOT, the distinguished chemist, has been appointed Minister of Foreign Affairs in the new French Cabinet. He was Minister of Education in the Cabinet of 1886-87.

IT is reported that the Paris Municipality have granted £800 to the Salpêtrière Hospital for the erection of new buildings in which to treat nervous and mental affections by electricity.

THE Board of Agriculture have appointed a Departmental Committee to consider and report upon the arrangements which it is desirable to make for the sale and distribution of Ordnance Survey maps. The committee consists of the following gentlemen:—Mr. W. Hayes Fisher, M.P. (Chairman), Mr. H. Hobhouse, M.P., Mr. W. A. M'Arthur, M.P., Mr. F. a'C. Bergne (Treasury), and Mr. T. H. Elliott (Secretary to the Board). Mr. J. J. Thomson, of the Board of Agriculture, will act as the Secretary to the Committee.

THE new public museum which has lately been opened at Kasan, well deserves the attention of archæologists for its beautiful collections, the gift of A. Th. Likhacheff. The collections comprise a considerable number of golden and silver bracelets, earrings, rings, as well as of various arms and implements from the once powerful kingdom of the Volga Bulgars, on the seat of which Kasan now stands. The modern decorative art of the Kasan Tartars, as well as the dress and implements of the Chuvashes, Cheremisses, and Mordves, are also very well represented; while nearly 1500 stone implements illustrate the Stone age on the Volga and the Kama.

THE Zoological Department of the British Museum (Nat. Hist.) has recently acquired (by purchase) an important series of British fossils from the cabinets of the Rev. P. B. Brodie, of Rowington, Warwickshire. The specimens mainly illustrate the fauna and flora of the Mesozoic period, among them being several valuable types described by Owen, Egerton, Buckman, Wright, Duncan, Carruthers, Woodward, and other palæontologists. Some of the rarer genera include remains of *Hyperodapedon*, *Mastodonsaurus*, and *Cladyodon* from the Keuper sandstone of Warwick, each of which will be now represented in the National collection for the first time, from that locality.

IN September of next year, the Smithsonian Institution, which has exerted an immense influence upon the development of science in America, and which has done more than any institution to make the results of scientific work known unto the ends of the world, will celebrate its jubilee. It is stated by Dr. Brown Goode, in a historical account of the Institution, that a special volume will be published to commemorate the event, and two memorial tablets will be erected in honour of the founder in the city of Genoa, where he died June 26, 1829: one in the English church, and one upon his tomb in the beautiful little English cemetery on the heights of San Benigno.

REUTER reports the occurrence of a severe and prolonged earthquake shock in Rome at 4.30 on the morning of November 1. The Central Meteorological Bureau states that the movement of the earth began with very slight tremors, lasting from four to five seconds. Subsequently a series of strong shocks, which continued for nearly eight seconds, occurred. After a calm of a few seconds slight undulations were perceptible for about eight seconds. Two clocks in the observatory stopped, and the old tower of the Roman College was cracked a little. At Rocca di Papa, near Rome, a violent undulatory shock was felt at 4.40. It lasted seven seconds, but caused no damage. Shocks were also felt at Anzio, Velletri, Tivoli, Civita Vecchia and Fiumicino, all in the vicinity of the capital. At the latter place the earth movement was especially strong.

WE have received from Prof. G. Vicentini, of Padua, some interesting copies of microseismographic records of a distant earthquake on October 20. The instrument with which they were obtained has been briefly described in a previous note (vol. li. p. 540). The first movements, which Prof. Vicentini attributes to longitudinal waves, began about 9h. 30m., Greenwich mean time (whether a.m. or p.m. is not stated), and lasted about twenty minutes. The second series of pulsations, which he regards as due to transversal vibrations, and each of which had a period of about thirty seconds, attained their maximum intensity about 10h. 15m., and lasted until about 11h. 30m. Somewhat similar pulsations were also registered on October 4, the longitudinal vibrations commencing between 10h. 25m. and 10h. 30m., and the transversal vibrations (of long period) after 10h. 50m. So far as we are aware, no great earthquakes are known to have occurred on these days. If the disturbances are of seismic origin, they must evidently be due to very violent shocks taking place in some distant region of the globe.

THE death is announced of Dr. Albert E. Foote, of Philadelphia. Dr. Foote was born at Hamilton, in 1846. After graduating at Courtland Academy, Homer, N.Y., he entered the class of 1867 in the University of the State of Michigan, where he took the degree of Doctor of Medicine. He spent some time as an instructor at Ann Arbor, and also as Assistant Professor of Chemistry and Mineralogy in the Iowa State College. He removed to Philadelphia in 1875. He was a life member of the Academy of Natural Sciences, of the New York Museum of Natural History, and the American Association for the Advancement of Science. Dr. Foote's wide correspondence and extended travels made him well known, especially among mineralogists. His exhibits and lectures at the American Exhibition in London in 1887, and attendance at the meetings of the British Association in several years, established lasting relations with many English mineralogists. He was one of the most enthusiastic and successful of collectors, and found much of the enjoyment of life in the collection and study of minerals and meteorites.

THE *Pioneer Mail* of Allahabad is always to the front when the claims of science to a fuller recognition in India have to be urged. A leading article, in its issue of October 10, calls attention to the need for a better recognition of scientific research than at present exists there. "Buried in the archives of the Asiatic Society of Bengal," remarks our spirited contemporary, "in those of the kindred British societies, and in a few journals of the elect, is a mass of scientific literature relating to the Anglo-Indian Empire with which its Government professes to have no concern. Most of this literally priceless work has been done by Government officials in such leisure as they have been able to snatch from the daily turn at the Government mill. The Civil Service has been rich in amateur 'pandits,' but their fame is not echoed from the rocks of Simla, though it resounds in European halls of learning. In India such men were looked at askance by the Bureaucracy, and relegated to desert places. Years ago the State spoilt an excellent geologist by converting him into a Government gardener, and did the same for another by gazetting him an ornithologist. And all the while there is that great mine of palæontological wealth in the Sewaliks lying fallow since the days of Falconer—the far-away time of Cautley and the Ganges Canal. In a few cubic feet of worm-eaten Government reports are to be found the bald details of measurements which represent the Government knowledge of Indian archæology. No one has followed in the footsteps of Fergusson; his monumental work is a classic alongside with the unopen and dust-laden works of Todd in Rajasthan and many another amateur. Not very long ago Government nipped in the bud any inclination on the part of their little Geological Department to travel into regions other than those of purely economical geology. Now that General Cunningham is no more, that sole key to the history of ancient India—numismatics—would speedily rust and be lost were it not for the enthusiasm of an amateur, who is left to struggle along as best he can. A noble effort, but a lasting reflection, nevertheless, upon an enlightened Government."

EFFORTS are being made to obtain funds for the erection of a memorial to the memory of the late Joseph Thomson, the African explorer. Subscriptions may be sent to Mr. S. W.

Silver, 3 York Gate, Regent's Park, or to Mr. J. Scott Keltie, 1 Savile Row, Burlington Gardens.

A FEW particulars with reference to the Pasteur Institute, from the *British Medical Journal*, are of special interest at the present time. The receipts budget of the Institute is as follows:—The interest on £48,000, which is the amount that remains of the ublic subscription (about two-thirds of the sum subscribed, or £80,000, was spent on the ground bought for the Institute and in building). From £800 to £1200 was granted by the Minister of Agriculture in recognition of the service rendered by the anthrax vaccine, by the treatment of swine fever, and by the supply of tuberculin and mallein. A subvention is granted the Minister of Public Instruction to pay the salaries of such of the Institute staff as were formerly attached to Pasteur's laboratory. Certain profits are made by the sale of the anthrax vaccine, and others sold at a very low price to veterinary surgeons, and they realise for the Institute an income of £800. The fees paid by the pupils who attend the lectures of the Institute are also paid into the Institute treasury. Dr. Roux's antidiphtheric service is annexed to the Pasteur Institute, but has a distinct budget. This service is organised at Garches, on the estate given by the Government to M. Pasteur for the purpose of carrying on his researches on rabies. Its revenue is furnished by the interest on the sum realised by a public subscription, and by a Government grant amounting this year to £3200. The services at the Institute are as follows:—Practical services, consisting of inoculations, &c.; the lectures in this service are given by Dr. Roux and Dr. Metchnikoff. The pupils are of two classes, "hearers" and "workers," who are allowed to work in the laboratories. The research laboratories are placed at the disposal of investigators, whose communications are published in the *Annales de l'Institut Pasteur*. The chiefs are—M. Duclaux for biological chemistry; M. Grancher, M. Charrin, and M. Chantemesse for rabies; M. Chamberland for microbic vaccinations and practical applications. There is a morphological laboratory under the direction of M. Metchnikoff, and a technical one under M. Roux. M. Nocard, professor at Alfort Veterinary School, directs a veterinary service annexed to the Institute. M. Duclaux is professor at the Faculté des Sciences. The course of lectures he previously gave at the Sorbonne are now held at the Pasteur Institute, where the Sorbonne pupils follow him. The Institute was founded in 1888, and retains its constitution and characteristics notwithstanding the death of Pasteur. His pupils will carry on the work.

THE late Mr. John Bell Sedgwick has bequeathed £300 to the Royal Institution in aid of the fund for the promotion of experimental research at low temperatures; and Sir Frederick Abel has given £50 to the same fund.

THE Manchester Museum public lectures continue to attract large audiences. This year there are five courses, each consisting of three lectures; and the first course was brought to a close on Saturday afternoon by an interesting discourse upon "Social Customs and Dwellings," the general subject being "The Elements of Anthropology," and the lecturer Prof. S. J. Hickson. The succeeding lectures are upon Mineralogy, by Dr. Burghardt; Botany, by Prof. F. E. Weiss; Geology, by Prof. Boyd Dawkins; and Zoology, by Mr. W. E. Hoyle. There are now seven handbooks upon the various departments of the Museum, one of which—a handy guide to the whole of the cases—is sold for a penny. The aim of the Professors is to render the lectures educationally valuable, as well as interesting; and the hands of the authorities will be strengthened by a recent grant from the Manchester Corporation of £400, which is to be annual.

THAT certain Hymenoptera and Homoptera secrete wax is well known, and a note by Dr. H. G. Knaggs, in the *Entomologist's Monthly Magazine* for November, indicates that this function can also be performed by Lepidoptera. An investigation of some cells of *Retinia resinana* proved them to contain a very appreciable amount of wax, which formed the lining of the cells. The nature of the lining was demonstrated by dissolving off the resin by immersion in cold rectified spirit, a fluid which appears to have little or no effect upon the wax, so that the latter was thereby exposed to view. "From this it seems to me," concludes Dr. Knaggs, "to be pretty clear that the larva is furnished with the power of secreting wax for the purpose of protecting itself from contact with the tenacious semi-liquid resin exuding from the wound in the fir bud; otherwise, it would inevitably become involved in the sticky medium. Previously to this, however, I was aware that the imagines of certain Lepidoptera contained wax, though I had then formed no idea as to the part played by it in the economy of the insect's life."

GOLD-MINING is showing signs of revival in Victoria, as in many other countries. Forty years ago the colony was the foremost gold-producer in the world, throwing even California into the shade. Although, however, its output has shrunk from over 3,000,000 ozs. in 1856 to 673,000 ozs. last year, it has now, according to the *Annual Report of the Secretary for Mines*, again become a progressive quantity, and the product in 1894 was greater than that in any previous year since 1885. This was due to exceptional causes, the granting to the unemployed of free passes by railway from Melbourne to the various gold-fields having added 15,000 labourers to the number of prospectors and "fossickers." Quartz-mining was less actively pursued in 1894 than in 1893, and the whole gain came from alluvial deposits. Of these, as usual, the most important were the "deep leads" or gravels contained in the beds of Pliocene streams now buried beneath lava flows. In Victoria these gravels are almost exclusively reached by shafts, the deepest of which, at Bendigo, is now down 3122 feet. The Government geologist reports that some extensive systems of deep leads have been discovered and traced out by borings, one system in particular, on the northern side of the Great Dividing Range and to the westward of the meridian of Melbourne, having an aggregate length of forty miles of leads. To work this an enormous capital would be required, and it is proposed to make it a national undertaking, subsidised by the Government.

A VALUABLE paper on the new rubber industry in Lagos appears in the Kew *Bulletin* of Miscellaneous Information (No. 106, October), from which source the following facts were obtained. It is well known that in West Africa there are numerous plants yielding commercial rubber. The chief of these are species of the Apocynaceous genus *Landolphia*, consisting of climbing shrubs, with stems four to six inches in diameter dividing above into numerous branches, and supporting themselves on neighbouring trees. From these, and similar plants, a very important rubber industry was started at the Gold Coast by Sir Alfred Moloney, K.C.M.G., in 1882; and although previous to that year no rubber whatever was exported from that colony, it had attained in 1893 to the annual value of £200,000. This is a remarkable and striking instance of the creation of a new industry by official action, and it deserves to be recorded. In 1882, Sir Alfred Moloney pointed out the possibilities of a similar rubber industry in Lagos, and suggested "the adoption of measures having for their object the addition of one more to the industries of the colony." The result of this was not immediately apparent. But in 1894 the present Governor of Lagos, Sir Gilbert T. Carter, K.C.M.G., induced a party of natives from the Gold Coast, experienced in rubber collecting, to go to Lagos to develop this valuable and importan industry. A new rubber-yielding tree, the native name of which is "Ire" or "Irai," was shortly afterwards discovered

to be abundantly distributed in the interior forests of the colony. The tree has been identified at Kew as *Kickxia africana*, Benth., and the history of its discovery, and the remarkable influence it has had upon the rubber industry, is full of interest, and illustrates the wonderfully rich resources of the forests of West Africa. The account also shows very clearly how these resources can be developed by judicious and intelligent action on the part of the Government.

A SPECIAL feature of the recent meeting of the British Association at Ipswich was the consideration given to agriculture and allied subjects. As already reported in our columns, a joint sitting of the Sections of Chemistry and Botany was held for the purpose of discussing the relations of agriculture to science. The discussion was opened by Prof. Warington, who read a paper on this subject. Mr. J. Hendrick, of the Glasgow Technical College, and Mr. M. J. R. Dunstan, the Director of Technical Education for Nottingham, also sent papers by way of contributions to the proceedings. One very good feature of this organised discussion was that copies of the opening paper had been freely circulated some time before the meeting, so that the speakers were prepared for the mode of treatment which Prof. Warington adopted. If this plan were more generally followed when discussions at joint sectional sittings were to be held, the value of such meetings would be greatly raised. In response to a widely-expressed desire, the three papers referred to, and a condensed report of the remarks made by the various speakers, have now been reprinted in pamphlet form, and can be had, at a trifling cost, from the Secretary of the British Association, Burlington House, or from the office of the *East Anglian Daily Times*, Carr Street, Ipswich. All who are interested in the agricultural question, from the educational or from the scientific side, will find much material for serious consideration in the various views expressed by a series of speakers of recognised authority.

DR. SIMPSON, Health Officer in Calcutta, in his annual report, refers at some length to Prof. Haffkine's anti-choleraic vaccinations, and expresses himself as very favourably impressed with the treatment, as far as can be judged at this early stage of the inquiry. Some interesting facts are quoted relative to the manner in which the progress of cholera in particular houses seemed to be arrested by inoculation. Thus, in one instance cholera attacked fatally one member of a household; two days later, eleven members of the family out of eighteen were inoculated. "It so happened," continues Dr. Simpson, "that cholera again breaking out in the house, attacking four persons, three of whom died, selected four of the seven not inoculated, while the eleven inoculated remained perfectly free." Again we read that two fatal cases of cholera and two of choleraic diarrhœa occurred in Katal Bagan Basti in a population grouped around the tanks. This outbreak led to the inoculation of 116 persons in the district out of about 200. Since the 116 cases were inoculated, nine more cases of cholera, of which seven were fatal, and one case of choleraic diarrhœa took place. All these ten cases of cholera occurred exclusively among the non-inoculated portion of the inhabitants, and not one of those treated with the vaccine were affected. Dr. Simpson recommends the Commissioners to give the system an extended trial, and he considers that such observations, if carried on in Calcutta on a large scale in its most affected parts during the next one or two years, would solve the question as to its efficacy. As regards the discomfort caused by the inoculations, he states that it is on the whole milder and of shorter duration than that of vaccination against small-pox. Two vaccines are used, one mild and the other strong, and for a complete vaccination two inoculations are necessary, first with the mild vaccine, which produces some pain at the seat of inoculation, or discomfort and fever for about one day; after a period of five days the second inoculation takes place with the stronger vaccine, which produces a similar form of malaise to that caused by the first inoculation. The harmlessness of the treatment has been established beyond question.

As one of the results of a long piece of work carried out in the botanical laboratory of Trinity College, Dublin, Mr. Henry H. Dixon believes that his preparations of the pollen-mother-cells of *Lilium longiflorum* before their first division show that origin of the double nuclear thread is not from the cleavage longitudinally of an originally single thread, but from the approximation of portions of the single thread, so that these portions come to lie more or less parallel to one another. When the thread breaks into the chromosomes the divisions affects both portions, so that each chromosome is composed of two more or less parallel pieces. These pieces may lie side by side, or may be fused together at one end while the other ends are somewhat parted asunder, or they may be bent in such a manner that they come to lie across one another in two or three places, or they may be fused together at both ends. As the chromosomes arrange themselves in the equator they become shorter and thicker, and they are so disposed that the plane of separation between their two parts lies vertically, and consequently they appear double when viewed from the polar aspect. At this stage, when seen from the equatorial plane, they have the appearance of short thick rods. Later on, horizontal fission takes place in each, beginning from the inner end. As this proceeds they assume the T-shape described by Belajeff. The daughter chromosomes have the V-shape as they leave the nuclear plate, having passed through stages similar to those described by this author. As they approach the poles each V-shaped chromosome cleaves transversely at the angle, and breaks into two short straight rods, so that at the poles there appear to be twice as many chromosomes as in the nuclear plate. Thus it appears probable, both from the origin of the two portions of the chromosomes forming the nuclear plate, and the subsequent division of the daughter chromosomes at the poles, that each chromosome of this mitosis corresponds to two chromosomes of previous nuclear divisions fused more or less completely end to end. The division following, to form the pollen-tetrads, was not observed in this plant, but it probably conforms in its details to the normal karyokinesis in plant cells, as in *Lilium Martagon* and *L. chalcedonicum* it was followed, and the normally-proportioned chomosomes undergoing longitudinal fission in the nuclear plate were observed.

A LONG paper on the working of iron and steel, by M. E. Demenge, appears in the *Revue Générale des Sciences* for October 15 and 30. The article is illustrated by twelve full-page plates, chiefly representing modern forging and rolling machinery.

IN *Botany Bulletin*, No. 11, of the Department of Agriculture, Brisbane, Mr. F. M. Bailey gives a complete list of the Freshwater Algæ of Queensland, including descriptions of several new species.

MR. G. MASSEE has reprinted from the *Annals of Botany* his paper on the "Spot-disease of Orchids," which shows that the disease is not of a parasitic nature, the initial cause being the presence of minute drops of water on the surface of the leaves at a time when the temperature is exceptionally low and the roots copiously supplied with water.

WE have received a further communication from Mr. Radcliffe, the inventor of the "38" puzzle (NATURE, No. 1352, p. 525), in which he shows how, by the sacrifice of his three extra symmetrical arrangements, the maximum number of 15 straight lines (all totalling to 38) can be obtained. He points out also some other symmetrical arrangements.

THE first edition of "Practical Physiology of Plants" (Cambridge University Press), by Mr. F. Darwin, F.R.S., and Mr. E. Hamilton Acton, was published a year ago. The work has been appreciated from the outset, and so great has been the demand for it that it has been out of print for a little time. A second edition has, however, just been published; but with our pleasure that the merits of the book have been recognised, must be mingled regret that the death of Mr. Acton should have prevented him from seeing its success.

THE forthcoming number of the *Physical Review* (November-December) will contain the following articles:—"Variation in Electric Conductivity of Metallic Wires in Different Dielectrics," by Fernando Sanford; "A Study of the Polarisation of the Light emitted by Incandescent Solid and Liquid Surfaces" (II.), by R. A. Millikan; "On Ternary Mixtures" (III.), by W. D. Bancroft; "On the Changes in Length produced in Iron Wires by Magnetisation," by L. T. More. Among the minor contributions will be: "The Limits of Pitch for the Human Voice," by W. Le Conte Stevens; "The New Physics Laboratory at Lille," by E. L. Nichols.

THE *Quarterly Journal* of the Geological Society (No. 204, November), just published, is illustrated by twelve plates. The contents of the number include a paper on the geology of Mount Ruwenzori and some adjoining regions of Equatorial Africa, by Mr. G. F. Scott Elliot and Dr. J. W. Gregory. Mr. A. Strahan explains overthrusts of Tertiary-beds in Dorset, and Mr. G. W. Lamplugh describes the "Crush-Conglomerates" of the Isle of Man, while Mr. W. W. Watts writes on the petrography of the same. The other authors and papers are: Messrs. W. Hill and A. J. Jukes-Brown, on the occurrence of Radiolaria in Chalk; and Dr. G. J. Hinde and Mr. H. Fox, on Radiolarian rocks in the Lower Culm Measures.

THE Meteorological Council have published the hourly means of the readings obtained from the self-recording instruments at the five observatories under their control, for the year 1891. The present volume contains the values for an additional observatory—Fort William, the low-level station of the Ben Nevis Observatory. An additional table has also been added to the series, containing hourly sunshine values, and in an appendix will be found the results of an hourly tabulation of the sunshine cards for the ten years 1881–90, for seven stations, illustrated by coloured plates. A summary of the hourly and seasonal variation of sunshine, based upon these values, was submitted to the Royal Meteorological Society, by Mr. R. H. Curtis, on June 19, a report of which appeared in our issue of the 27th of that month (p. 215).

IN connection with the recent jubilee celebrations at the Royal Agricultural College, Cirencester, which were attended by the Prince of Wales, as patron of the institution, a special effort was made to issue a number of the *Agricultural Students' Gazette* which should be worthy of the occasion. Several past professors of the college responded to the editor's call for co-operation, and accordingly we find articles on "Anbury, Club-root, or Finger-and-toe," by Mr. W. T. Thiselton-Dyer; on "The Rise and Progress of Veterinary Science in its Relation to Agriculture," by Prof. G. T. Brown; and on "Meadows and Pastures," by Dr. W. Fream. Old students are represented by Sir Jacob Wilson, who writes on the "Progress of Agricultural Education." Prof. Warington has a paper on "Organisms in Soil assimilating Nitrogen from the Atmosphere"; and amongst other subjects dealt with are the breeding of Shires, our meat supply, estate fences, curd making, chlorine in rain-water, and Samuel Hartlib and his "Legacie."

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mrs. Jackson; three Red-backed Pelicans (*Pelecanus rufescens*) from East Africa, presented by Mr. F. E. C. Remington; two Verticillated Geckos (*Gecko verticillatus*) from Burmah, presented by Mr. H. Champion; a Common Boa (*Boa constrictor*) from South America, presented by Mr. F. J. Mitchell; a Whimbrel (*Numenius phæops*), European, presented by Messrs. Mason; a Black-faced Spider Monkey (*Ateles ater*) from Eastern Peru, a Brown Capuchin (*Cebus fatuellus*) from Guiana, deposited; two Black-tailed Flower-Birds (*Anthornis melanura*) from New Zealand, two Silver Pheasants (*Euplocamus nycthemerus*) from China, purchased; a White-tailed Gnu (*Connochætes gnu*, ♂) from South Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

STARS WITH BRIGHT AND DARK HYDROGEN LINES.—In his observations of the spectrum of the well-known bright line star γ Argus during 1893–94, Prof. Campbell noted the remarkable fact that whilst the red line of hydrogen was quite bright, the hydrogen lines in the violet were dark. The same peculiarity was also observed in the spectrum of η Tauri.

Since then Prof. Campbell has observed the spectra of all the available stars showing the F line bright in their spectra, and in some cases has secured successful photographs; from a consideration of the results obtained, he claims to have established the following points. (1) Some stars contain both bright and dark hydrogen lines. (2) The bright lines in such stars are those of greater wave-length, the dark lines are those of shorter wavelength. (3) The intensities of the bright lines decrease as we approach the violet. (4) The intensities of the dark lines increase as we go to the violet. (*Astrophysical Journal*, vol. ii. No. 3, p. 177).

In the case of γ Cassiopeiæ, Prof. Campbell finds the bright hydrogen lines to diminish very rapidly in intensity in the more refrangible part of the spectrum, and observes that they are situated within broad dark hydrogen lines; he does not, however, appear to have noticed the additional feature of the duplication of the bright lines in the spectrum of this star as photographed at Kensington (NATURE, vol. li. p. 425), although he records a similar appearance in the spectrum of ϕ Persei.

As to the explanation of the somewhat strange behaviour of the hydrogen lines, Prof. Campbell revives a suggestion due to Prof. Frost, namely, that the *selective* absorption of a star's atmosphere may be greater for the more refrangible rays, just as the *general* absorption of the sun's atmosphere is greater for such rays, the character of a spectrum being the resultant of radiation and absorption phenomena.

As first pointed out in connection with the meteoritic hypotheses, these stars represent a very early stage in sidereal evolution, and we note that Prof. Campbell adopts this view. He finds also that the variations of spectrum in passing from one star to another indicate that many steps in the evolutionary process are represented.

PARALLAXES OF STELLAR SYSTEMS.—The possibility of determining the parallax of a binary star, and hence the dimensions and mass of the system, by a spectroscopic observation of the relative velocity in the line of sight, was first pointed out by Fox Talbot in 1871, but the suggestion has not yet borne fruit. Some hesitation in taking up this interesting piece of work has no doubt been due to the smallness of the velocity to be measured in most cases; but now that such a high degree of accuracy is attainable, there is no longer any reason to suppose the method impracticable. A very simple way of computing the parallax from an observed velocity in the line of sight was introduced by Dr. Rambaut a few years ago, a knowledge of the orbital elements being assumed (*Monthly Notices*, vol. l. p. 302). This paper seemed to supply all that was needful in the way of facilitating the necessary computations; but Dr. See has recently treated the subject somewhat differently (*Ast. Nach.*, No. 3314). The hodograph of an ellipse being a circle, the velocity at any point in the ellipse is represented by the radius vector of the hodograph which is parallel to the tangent to the orbit at the point in question. The radius of the hodograph can be determined from the spectroscopically observed velocity, and the value of the velocity in the line of sight can then be predicted

for any instant whatever. From the orbital velocity it is easy to deduce the length of the semi-axis major of the orbit, and the parallax is equal to the semi-axis major in seconds of arc, divided by the length of the same when expressed in astronomical units. The sum of the masses follows from the ordinary application of Kepler's third law. Dr. See lays special stress upon the importance of these investigations being taken up practically, as they will furnish us with "an absolute parallax exact to the highest degree," and will also enable us to apply a rigorous test of the universality of the law of gravitation. It is known already, from micrometrical measures, that Kepler's second law holds good for binary stars, and therefore that the force is central; but it remains to be shown that the principal star is in the focus of the real ellipse.

THE SOLAR PARALLAX.—Among the various methods suggested as suitable for the determination of the solar parallax, that afforded by the parallactic inequality in the motion of the moon deservedly takes a high place. The reason is that in this particular term the parallax of the sun is multiplied by a coefficient which increases the quantity to be determined in the approximate ratio of 1 : 15, so that an error of a tenth of a second in the inequality would not produce an error of one-hundredth in the parallax sought. But in deriving the solar parallax it is necessarily assumed, that the relation between these quantities is accurately given by theory. Unfortunately there has been a discrepancy between the coefficients derived by Hansen and Delaunay, and the accepted explanation has not been the correct one. In order to ensure identity between Hansen and Delaunay it was necessary to suppose than an error existed in the highest term computed by Delaunay, and that the deviation of the remaining terms from the general character of the series did not exist. Recent work by Mr. Hill and Prof. Brown has, however, confirmed the accuracy of Delaunay's theory so far as this particular term is concerned, though it leaves a general doubt on the legitimacy of neglecting the higher terms in some of the series in other parts of the theory. Prof. Newcomb points out (*Astronom. Jour.* No. 356) that this more recent discussion of Messrs. Hill and Brown demands an increase on the theoretical value of Hansen, on which he had previously relied, of $0''\cdot30$, and consequently a diminution in the solar parallax of $0''\cdot021$ giving the corrected value of $\pi = 8''\cdot773$.

THE EPPING FOREST MUSEUM AT CHINGFORD.

THE opening of this museum, which we announced in our last week's issue as having been fixed for Saturday, November 2, was in every respect an interesting ceremony, and marks a period in the history of the Essex Field Club, of which this active society may well feel proud. Two or three years after the foundation of the Club in 1880, an informal meeting was held at the residence of Mr. E. N. Buxton, with a view to starting such a local collection, but the Conservators at that time had not long been in charge of the Forest, and they did not see their way to giving house-room for the museum in the old lodge known as "Queen Elizabeth's." The founders of the Club, however, have never lost sight of the desirability of having such a collection in the Forest district, and in February 1894, a special meeting of local residents and others was convened, and a local sub-committee formed for the purpose of forwarding the scheme. A subscription list was opened, and a sufficient sum raised to warrant another application to the Conservators for the use of Queen Elizabeth's Lodge. This was granted, and the Banqueting Room, which from time immemorial has been unoccupied and devoid of fittings, has now undergone transformation into a museum, which was declared open to the public as a part of Saturday's proceedings. The arrangement of the collections, illustrating the natural history, geology, archæology, and topography of the Forest, has been entirely carried out by Mr. William Cole, the Hon. Secretary of the Club, aided by his brothers and a few zealous workers who gave their co-operation, notably Messrs. W. Crouch, I. Chalkley Gould, A. Greenhill, and others. On Saturday afternoon a very representative gathering of scientific men took place at Chingford, to assist at the opening ceremony. The members and guests, comprising among the former Sir William Flower, Mr. Edward North Buxton, Profs. R. Meldola and G. S. Boulger, Mr. J. E. Harting, &c., and among the latter a large number of the Epping Forest Committee of the Corporation of London, were received by the President of the Club, Mr. David Howard, in a room adjoining the museum. After a few introductory remarks by the President, Sir William Flower addressed the meeting on the general subject of local museums and the advantages to be derived from their establishment. Mr. Deputy Halse, the Chairman of the Epping Forest Committee, then expressed, on behalf of the Corporation, the satisfaction which they all felt in being associated with the Essex Field Club in the movement, and declared that from Monday, the 4th, the collections would be available for public inspection. The party then proceeded to view the museum, and great satisfaction was expressed at the large amount of material which had been brought together in a comparatively short time and with very modest financial means. Mr. Greenhill's collection of flint implements from the valley of the Lea, Mr. T. Hay Wilson's set of drift rock materials from the local glacial gravels, Mr. Crouch's shells of the Dengey Hundred, the cabinets of Forest flowering plants, fungi and insects, and the interesting set of relics found during the Club's explorations of the Forest earthworks, were all much admired. A pamphlet by Mr. Chalkley Gould, being one of a proposed series of museum handbooks, was distributed at the meeting. The author in this pamphlet gives a description of the Romano-British station at Chigwell in illustration of the specimens which he has contributed to the museum. After the inspection the party assembled for tea at the Royal Forest Hotel, some eighty or ninety members and visitors being present. At a meeting of the Club, held after tea, the President moved a vote of thanks to Mr. William Cole and his coadjutors for the large amount of work which they had voluntarily done on behalf of the museum. This was warmly seconded by the Rev. A. F. Russell, the rector of Chingford, who is chairman of the local sub-committee. Mr. Cole having acknowledged the vote of thanks, Mr. A. Smith Woodward (of the British Museum) then gave a short address, in the course of which he pointed out the essential requirements that the museum should fulfil in order to be of real use, and commented most favourably upon the arrangement of the collections, their contents, and their mode of display. Sir William Flower expressed his concurrence with Mr. Woodward's remarks, and made some further observations and suggestions, especially dwelling upon the importance of taking steps to insure the permanence of the museum when those who had laboured so well for its foundation were no longer able to carry on the work. In the course of his remarks he paid a high tribute to the general work of the Essex Field Club, of which he had been an honorary member almost from the time of its foundation. Prof. Meldola, in proposing a vote of thanks to Mr. Deputy Halse, pointed out that the element of permanence to which Sir William Flower had alluded was most likely to accrue from their association with the Epping Forest Committee. This vote having been seconded by Mr. E. N. Buxton, and replied to by Mr. Halse, Mr. Harting made some remarks on the danger of encouraging promiscuous "collecting" by schoolboys, and the proceedings terminated. Favoured by an exceptionally brilliant autumnal afternoon, the meeting was a distinct success, and must have given great satisfaction to its promoters. The museum is necessarily small, but a good beginning has been made, and the time may be looked forward to when increased accommodation will be required. The feature which most strongly commends it to students of natural science, and lovers of the Forest generally, is the purely local character of the collections. No more appropriate use of Queen Elizabeth's Lodge could possibly have been made, and the Corporation of London have done wisely in allowing the Essex Field Club to found an institution which, however small and unpretentious, is, even as at present appointed, a distinct boon to all frequenters of the Epping Forest district.

CONCENTRATION OF GOLD ORES.[1]

WHEN gold mining is a new industry in any country, the methods of extraction are often somewhat rough and ready. With great quantities of rich ore waiting for treatment or easily obtainable, the mill-man is usually intent on obtaining the greatest possible quantity of bullion in a short time, rather than on establishing a good system of reduction, which in the

[1] "Report on the Loss of Gold in the Reduction of Auriferous Veinstone in Victoria." By Henry Rosales. (Issued by the Department of Mines, Melbourne, 1895.)

long run would extract the maximum percentage of gold per ton at the minimum cost. It matters little to him how much gold runs off in the tailings into the nearest stream, so long as enough is extracted to pay expenses and yield a handsome profit. When, however, the industry becomes firmly established, the aspect of affairs is changed. The richer mines can afford to spend something in endeavouring to improve their practice; the poorer ones have their very existence threatened by the loss of 30 or 40 per cent. of the gold, which has been raised from a great depth, only to be left on the dumping ground.

This stage has long been reached in the older gold fields of Australia, such as those in Victoria, where the industry has always been carefully nursed by the Government. One of the latest proofs of the solicitude of the Victorian Department of Mines is the issue of this report of Mr. Rosales, the veteran expert on concentration, who gained a Government prize for an essay on the subject as long ago as the year 1861. The report deals with the concentration of tailings from the stamp battery, and although it is specially applicable to Victoria, nevertheless it contains much information and many suggestions which deserve careful study by metallurgists in all parts of the world, and may be particularly valuable to the workers in South Africa.

In Victoria, as in many other countries, the majority of the gold ores found are "free-milling," yielding a fair percentage of their gold when amalgamated with mercury. The usual method of treatment is to crush the ore in a stamp-battery, a little mercury being added in the mortars, and to pass the pulp over amalgamated copper plates, by which most of the free gold is retained. The "battery sands," still containing a little free gold and a varying percentage of auriferous sulphides of the heavy metals, are then treated by various machines, such as canvas tables, vanners, percussion tables, blanket and wooden strakes, and revolving buddles, with a view to separate the heavy particles in which the gold is contained from the lighter worthless gangue. The concentrates are treated by grinding to impalpable pulp with mercury in iron pans, by chlorination or by smelting, according to the nature of the sulphides and to the other conditions.

The tailings from the orthodox concentrating machines would be allowed to run to waste if it were not that, on almost every mine in Victoria, they are compelled to run the gauntlet of the simple contrivances of a few Chinamen, who pay tribute to the mine-owner for the privilege of taking his leavings, and who extract enough gold to provide themselves with a living. Nevertheless it was stated in 1889, on the very high authority of the late Government analyst, Mr. J. Cosmo Newbery, that the tailings of the quartz-mining districts, even after passing the Chinese tables, contained in general from two to two and a half dwts. of gold per ton—some 15 per cent. of the amount originally contained in the ore. The gold thus lost is estimated as being of the value of over £350,000 in the year 1894, and a similar state of things is unfortunately only too prevalent in other countries.

Experts are agreed that it is the methods of concentration which are chiefly answerable for the continuance of this unsatisfactory state of things, not so much because the machines now at the disposal of the metallurgist are defective, as that in many cases they are set to do work for which they are inappropriate, although capable of dealing effectively with certain classes of material. In particular, the neglect on the part of metallurgists to classify the crushed ore according to size has been fatal to good concentration in a countless number of cases, and this mistake has not yet been generally rectified.

Let us suppose that a gold ore has been crushed so as to pass through a screen equivalent to a wire-sieve with thirty holes to the linear inch. The particles of ore are of all sizes, ranging from those which can just pass through the screen down to perfectly impalpable powder. From 20 to 50 per cent. would easily pass through a 100-mesh sieve, and a part of the ore, the "slimes," is so finely divided that it settles in still water with great difficulty. In spite of this, the whole mass, without any classification, is perhaps, after treatment with blankets, hurried over some one type of concentrator favoured by the manager, and the tailings allowed to escape without further treatment.

For example, a percussion table with "end-blow" is used, and the coarser particles of pyrites are readily separated from the remainder of the ore by its action. It usually happens, however, that the valuable sulphides, being softer than the quartz and other constituents of the gangue, are in the main more finely pulverised than the latter, so that the slimes are the richest parts of the ore, and these, under the circumstances, will almost all escape. Thus at the Johnson's Reef Mine, Eaglehurst, it was found that the "slimes," though constituting only 3 per cent. of the pulp, contained 21 per cent. of the gold, while 44 per cent. of the pulp, which was retained on a 60-mesh sieve, consisted mainly of quartz grains, and was absolutely worthless.

Or, in the alternative, the battery sands may be sent directly to some travelling belt table, such as the Frue vanner—a machine capable of doing splendid work in saving rich slimes—with the result that the coarser particles, valueless in themselves, interfere with its efficiency. Mr. Rosales cites the case of a mine at Ballarat, where the costly Frue vanners, which had been set to treat unclassified battery sands, were discarded in favour of the cheaper percussion tables, the fact being that neither concentrator could be expected to save the pyrites properly, the vanner being no more fit to treat coarse material than the percussion table is adapted to concentrate slimes. It would have been better to use the two machines successively on the same material, although even then, in the absence of classification, losses could not have been prevented.

Mr. Rosales has not been content to criticise, but has added a sketch of a complete system of concentration, which, with modifications, would be applicable to almost every gold ore likely to be met with. The keynote of the system is classification, and he can hardly be accused of laying too much stress on it, seeing that it has been neglected more generally than any other consideration in the past. He favours hydraulic classifiers (inverted pyramidal or pointed boxes of various forms) for separating the slimes from the sand; but, on the other hand, he considers that the division of the sand itself into two or three classes, according to the size of the grains, is best effected by revolving screens or trommels.

This view will undoubtedly be called in question. It is rare that a finer screen than one containing twenty holes to the linear inch is fitted to these machines, and although 60-mesh screens have been employed, the smallness of the capacity of trommels supplied with such fine sieves, and the great cost of repairs caused by their rapid wear, seem to render it unlikely that they will ever come into wide use. In revolving screens the effective surface operating at any one time is only a few inches wide, and, if they were fitted with 100-mesh sieves, it is to be feared that continuous clogging would reduce their capacity almost to the proverbial teaspoonful. There seems no adequate reason why the cheap, handy, rapidly-acting pointed boxes should be passed over, and if Mr. Rosales would press these, instead of the trommels, on Australian mill-men, he would perhaps find a more ready acceptance of his suggestions. It is true that when pointed boxes are used, the particles of ore in each class are "equivalents" (*i.e.* those falling at an equal rate in water), and not equal in size, particles of high density being left mixed with somewhat larger ones of lower density, but the classification is usually sufficient for the purpose.

For the rest, Mr. Rosales seems to lay more stress on efficiency than on cheapness. When, as in his complete system, nearly twenty different machines, without counting duplicates, are at work, each with a different purpose, in removing the auriferous sulphides from one kind of ore, the loss of gold may be reduced to little or nothing, but it is evident that the extra amount saved is not all clear gain. An additional percentage of gold may often be obtained at a loss, even by an automatic machine if it is costly to buy and to keep in repair.

No sudden drastic changes, however, are proposed by Mr. Rosales. The losses of gold in Victoria and elsewhere are undoubted, and until it has been shown that they cannot be profitably reduced, no shirking of the matter is admissible. Tests on each mine by sieving and assaying in the laboratory (which, alas! too often is non-existent) can alone show in what direction the practice may be improved, and, if proper attention were paid to the slimes only, many gold mines would have a much brighter outlook than at present.

In conclusion, a word may be said in protest against the unscientific and misleading Australian (and English) method of reporting assays of gold ores. The actual weight of gold extracted from the sample of ore is seldom recorded, and the probable error is quite undiscoverable. An observed weighing of 0·001 grain may be reported as 15 grains per ton, or may appear as two, three, or more times this amount. In every case the unit in the report is much smaller than that used for the observation. What analytical chemist would be guilty of such practices in his other work?

T. K. ROSE.

A DESTRUCTIVE PLANT PARASITE.[1]

A DISEASE of vine-leaves, characterised by the presence of brown or blackish blotches, which frequently spread over the entire surface of the leaf, has been known in European and American vine-growing districts under various provincial names for some years. This disease, known in France as *brunissure*, was investigated by Viala and Sauvageau, who concluded that it was due to the presence of a parasitic organism to which the name *Plasmodiophora vitis* was given. Prof. Debray's researches show that brunissure is far more generally distributed than was hitherto suspected, having been detected by this observer in plants belonging to forty-two natural orders. In like manner, the leaf is not the part most frequently attacked, as supposed by Viala, but root, branch, flower, and in fact every portion of a plant is liable to attack. Owing to the absence of spore-formation, zoospores, nuclei, and slender pseudopodia, coupled with the fact that, although a parasite, there is no trace of malformation of the host, Debray considers that the organism under consideration cannot be included in the Plasmodiophoræ, nor in any other recognised family, and proposes for its reception a new family, Pseudocommideæ, and a new genus, *Pseudocommis*, allied to Vampyrellæ and Myxomycetæ. The supposed organism when in plant cells is difficult to distinguish from the protoplasm of the cell, and more especially the nucleus; it is, however, more refringent, and usually remains intact after the protoplasm has been destroyed by the use of eau de Javelle. Iodine-green and methylene-blue give a green and blue stain respectively; the most certain reaction, however, is said to be chlor-iodide of zinc, which gives a yellow or brown colouration to the plasmodia. The organism is met with under various forms in the cells of the host, never occurring in the intercellular spaces; the plasmodium may be intimately mixed with, and almost indistinguishable from the protoplasm of the cell, or distinct from the cell-contents and densely vacuolate, or finally, in assuming a spherical form, perfectly homogeneous, or with a few spherical vacuoles. Under certain conditions the plasmodium travels from the interior of the cells of the leaf or other part of the plant to the surface, where it appears as a slimy or gummy secretion, and by this means passes on to other parts of the plant which are attacked. Sometimes the external plasmodium becomes hardened into wax-like masses or cysts, which are considered to represent a resting-stage. The appearance and spread of the disease is much influenced by meteorological conditions, a sudden chill favouring its development. No preventive based on experiment is given, but it is suggested that badly diseased parts should be removed, and the external migration of the parasite checked by a dusting of powdered lime.

If Debray's observations prove to be correct, we have in *Pseudocommis* the most universally diffused and destructive of plant parasites hitherto known.

SCIENCE IN THE MAGAZINES.

EVERY individual, as Prof. Milnes Marshall used to say, climbs up his own genealogical tree. Embryology shows how human lineaments are developed from a widely typical animal form, and evidences of the same relationship can be obtained from the study of the infant after birth. In the *Fortnightly*, Prof. Sully pleads for such study. "Ours is a scientific age," remarks he, "and science has cast its inquisitive eye on the infant. We want to know what happens in the first all-decisive two or three years of human life, by what steps exactly the wee amorphous thing takes shape and bulk, both physically and mentally. And we can now speak of the beginning of a careful and methodical investigation of child nature by men trained in scientific observation. This line of inquiry, started by physicians, as the German Sigismund, in connection with their special professional aims, has been carried on by a number of fathers and others having access to the infant, among whom it may be enough to name Darwin and Preyer." The biologist is able to use the physical development of a child to show man's kinship to the lower animal world, and the development of an infant's mind indicates to the psychologist how the mental history of the race has been evolved. It does not need a very acute observer to see the intellectual and moral resemblances between the lowest existing races of mankind and children. Several anthropologists have studied this phase of child-life, and have found it full of interest. The difficulty is to get systematic and scientific observations of children. Prof. Sully shows that the work is worth doing, and indicates some of the lines of study to be followed; all that is needed is methodical and trustworthy registration of the successive stages in the child's development.

A second article in the *Fortnightly* is a reply by Prof. Karl Pearson to an article in the September number of the *Review*, where Dr. St. George Mivart attempted to describe the limits of scientific knowledge and inquiry, and to show that many teachers of science were dogmatic, or "denominational," as he called it. Two other articles in which some of our readers may find interest are "Brahminism and the Foundations of Belief," by Vamadeo Shastri, and "Vegetarianism," by Mr. T. P. Smith.

An article on Pasteur, contributed by Profs. Patrick Geddes and J. A. Thomson to the *Contemporary*, is a readable and fairly full statement of his personal life and scientific work. The authors thus sum up Pasteur's legacy to the world: "There is the impulse which he gave, after the successful organisation of his own Institute, to the establishment in other countries of similar laboratories of preventive medicine, and, one may also say, of experimental evolution. There is his educative work at Strassburg and Lille, at the École Normale and the Sorbonne, and, above all, in the smaller yet world-wide circle of his immediate disciples. To general biology his chief contribution has been the demonstration of the part which bacteria play, not only in pathological and physiological processes, but in the wider drama of evolution. To the chemist he has given a new theory of fermentation; to the physician, many a suggestive lesson in the etiology of diseases; and a series of bold experiments in preventive and curative inoculation, of which Roux's treatment of diphtheria, and Prof. Fraser's new remedy for snake-bites, are examples at present before the public; to the surgeon, a stable foundation, as Lister acknowledged, for antiseptic treatment; to the hygienist, a multitude of practical suggestions concerning water-supply and drainage, disinfection and burial. On brewer, distiller, and wine-maker he has forced the microscope and its results; and he has shown both agriculturist and stock-breeder how some, at least, of their many more than ten plagues may be either averted or alleviated." In the same *Review* Mr. Herbert Spencer traces the development of the judge and lawyer, and points out the relations between the priestly and judicial functions. There is also a forcible and philosophical reply by Father Tyrrell to Miss Cobbe's utterances in the October number. We content ourselves with giving two of the thirteen points upon which Father Tyrrell bases his position; they are: (1) as animals vary in sensibility, our duties concerning them vary also; (2) in the abstract, vivisection is not only permissible but laudable in certain conditions. Whether these conditions are or can be realised is a matter of opinion. He concludes: "Whatever one may think of the old-fashioned psychology on which this system rests, no one can deny that it is at least coherent and in keeping with the common sense of the best part of mankind, and that it offers a full and firm basis for a humane and reasonable treatment of animals, without entailing any of those hopeless problems which Miss Cobbe has to encounter in the application of her system."

A fine portrait of the late Prof. von Helmboltz, taken on the day of his last appearance in the lecture room, by C. Riborg Mann, appears in *Scribner*, accompanied by a brief summary of his leading contributions to science. The circumstances under which the photograph was taken are thus stated by the author: "At the close of his lecture on Saturday, July 7, 1894, Prof. von Helmholtz, at my earnest request, remained a few minutes in the class room and allowed me to photograph him. He stands as he was accustomed to appear before his students, the formulas as he had just written them remaining on the blackboard as a suitable background. By a strange working of fate, that was the last day on which he lectured, excepting one, when he gave some matter supplementary to this occasion; and this is his last photograph." A paper entitled "The Logic of Mental Telegraphy," contributed by Prof. Joseph Jastrow to the same magazine, should be taken to heart by a gullible public. Nothing is said about the attempted experimental tests of thought-transference, which may be worth investigation, but it is shown that coincidences will account for the possibilities of mental telegraphy believed in by the popular mind.

A few reminiscences of Huxley's habits and work at the

Royal College of Science, South Kensington, are contributed by Prof. G. B. Howes to the October number of the College's *Magazine*, and are accompanied by an excellent portrait of Huxley. This article throws some interesting side-lights upon Huxley's great personality, especially with reference to his bearing towards his students and subordinates.

A passing allusion will suffice for the remaining articles of scientific interest in the magazines that have reached us. *Longman's* contains a popular description of the making of kelp, by Mr. D. J. Robertson, and also a paper on the disappearance of gulls from "Pallinsburn Gull Pond," by Mr. P. Anderson Graham. In *Good Words* Sir Robert Ball writes on "Halley," Sir Herbert Maxwell, Bart., pleads for the preservation of the "Fowls of the Air," and the Marquis of Ormonde describes a short cruise to Norway and Spitzbergen. The *Sunday Magazine* contains the concluding paper by "Eha," on "Voices of the Indian Night." *Chambers's Journal* has, among the subjects of its popular articles: "The Coal of the World," "Migrations of Fish," "Some Modern Uses of Glass," and "A Bundle of Paradoxes." The *Strand Magazine* has a number of graphical representations of statistics referring to the coinage productions of the Royal Mint, by Mr. J. Holt Schooling. The *National* contains a brief appreciative note on Pasteur's work. In addition to the magazines mentioned, we have received the *Quarterly Review*, *Century Magazine*, *Humanitarian* (in which occurs a paper by Prof. W. F. Barrett, on "Dynamic Thought"), and the *English Illustrated Magazine*.

THE GEOLOGICAL SURVEY OF THE UNITED KINGDOM.[1]

SUMMARY OF THE CHIEF SCIENTIFIC RESULTS OBTAINED DURING THE YEAR 1894.

I. *England and Wales.*

THE survey of the Lower Silurian rocks of the Isle of Man has been continued by Mr. G. W. Lamplugh, who finds that the Skiddaw slates of this island, although they possess much lithological variation, are essentially the same mass throughout and are hardly likely to disclose any base to the series. Nor has it been possible to trace any sub-divisions, equivalent to those in the Lower Silurian rocks elsewhere, owing to the absence of fossils.

Reference was made in the previous Report (1893) to certain conglomerates or breccias which it was suggested may have been produced by the breaking up of sandy slates and grits under intense shear strain. These remarkable rocks have been found during the past year to attain an importance altogether unsuspected. Mr. Lamplugh has traced them in definite bands following the prevailing strike of the Skiddaw slates, and generally intercalated between an argillaceous and a more or less arenaceous group of strata. He has found one band to run continuously for eight miles, and thereafter, somewhat less clearly, for four miles further.

In the area of South Wales considerable tracts of Old Red Sandstone have been mapped during the past year by Mr. J. R. Dakyns and Mr. A. Strahan; and so far the following local subdivisions have been recognised:—

(3) Grey quartz-grits and conglomerates with some red sandstones. This group forms the uppermost of the whole series.

(2) Massive red sandstones with some conglomerates and a few red shales, as well as occasional grey sandstones and thin limestones (cornstones).

(1) Red and variegated marls with bands of soft red sandstone and thin limestones (cornstones).

These three sub-divisions pass into each other.

In Devonshire and Cornwall the re-survey of the Devonian formation and associated igneous rocks has been continued by Mr. Ussher, who has recognised that Upper Devonian strata are largely developed in the southern parts of these counties. Thus they are found skirting the Dartmoor granite, from Kingsbridge Road to Shaugh Prior, not far from Plymouth. In the Plymouth district, they consist of slates with local volcanic materials and a mass of porphyritic diabase at Ford, near Devonport. As they range into Cornwall, they present some specially interesting features. Besides retaining their evidence of contemporaneous volcanic action, they have yielded fossils which prove their stratigraphical position and allow of their being correlated with the Upper Devonian group of other regions.

The progress of mining, since first the maps of the coal-fields were published, has been so great that many of these maps have become more or less obsolete. It is therefore highly desirable, from an industrial and national point of view, that the surveys of our mineral fields should be revised, in order to place within reach of the mining community, and of the public generally, an accurate representation of the various coal-fields on which so much of the material prosperity of the country depends.

The re-survey of the great coal-field of South Wales has now been in progress for three years, and during the past year that of the North Staffordshire and Leicestershire fields has been begun.

During last summer certain improvements were made in the mapping of the Whitehaven district, particularly in regard to the boundaries between the formations and the positions of the faults. One of the most interesting points in this re-examination, made by Mr. A. Strahan, was the proof obtained of the existence of two distinct systems of faults, the one older than the Permian period and running from south-west to north-east, the other later than that period and trending from south-east to north-west. This fact had been previously insisted upon by Mr. J. D. Kendall, to whom the Survey is greatly indebted for his generous courtesy in supplying all the information which he had amassed during a residence of many years in the district as a mining engineer.

The chief work of the past year among the Cretaceous formations has been the tracing, by Mr. Jukes-Browne, of the various sub-divisions of the Chalk over tracts of the southern counties where they had not been previously mapped. Apart from its scientific interest this re-survey of the Chalk is of great economic importance. The maps will henceforth show at a glance the distribution of the various members of the Chalk, and thus will furnish accurate information for the guidance of those who have to sink wells or deal with the water-supply and drainage of the wide chalk-districts of the south of England.

Mr. Whitaker and Mr. Reid have continued the revision of the Tertiary strata in the Hampshire Basin.

During the past year the survey of the Superficial Deposits for the construction of an agronomic map of the country has made good progress in the midland and southern counties, and much new information has been obtained with regard to the extent of the drifts in Monmouthshire and South Wales.

In the valleys that intersect the South Wales coal-field, and chiefly end in the broad dip-slopes of the northern outcrop of Millstone Grit, much boulder-clay as well as gravel has been noticed by Mr. Gibson. It is almost entirely of local origin. That these uplands were overspread with ice is shown by the occurrence of glacial striæ on the Millstone Grit at a height of about 1500 feet above the sea. Further proof that the ice must have existed in considerable mass has been obtained in the excavations of some new waterworks at Nant-y-bwch, where a hill of sandstone upwards of 200 yards in length has been found to be a transported mass. Though its bedding is only slightly disturbed, yet the whole mass has been ascertained to lie upon boulder-clay, and must therefore be regarded as a huge boulder.

In the Isle of Man, Mr. Lamplugh has observed that the marked distinction referred to in the previous Report, between the insular drift of the hills and the extra-insular drift of the low ground still continues. The relative distribution of these drifts seems to prove that both are of truly glacial origin. Most of the deeper glens in the Isle of Man were probably filled with local glaciers before the coming of the great south-flowing ice-sheet which afterwards overrode the island up to its highest summits. As shown by numerous striæ observed on the Skiddaw slates, the general march of the ice during the height of the glaciation seems to have been from some point west of north, instead of east of north, as usually stated. A bed of fine warp or silt in the glacial series of Kirk Michael may prove to be of some economic value. It has been locally used in past time as a fuller's earth, and an effort is now about to be made to introduce it to a wider market for the same purpose.

II. *Scotland.*

As announced in the previous Report, all the tracts of Lewisian gneiss on the mainland, from Cape Wrath to the Kyles of Skye, have been mapped, but there are many displaced tracts or slices of that formation which lie to the east of the great line of com-

[1] Extracted from "Annual Report of the Geological Survey by Sir Archibald Geikie, D.Sc., LL.D., F.R.S., Director General," published in the *Report of the Science and Art Department* for the year 1894.

plication, and have undergone more or less deformation in the course of the gigantic earth-movements which placed them in their present positions. So far as at present known, no unmoved tracts of the oldest gneiss are to be looked for in the regions of Ross-shire and Inverness-shire yet to be mapped, but there may be many more or less recognisable disrupted masses among the crystalline schists of that region.

The only area where any of the Lewisian gneiss was mapped last year, on the western or undisturbed side of the great line of displacement, lay in the Island Raasay, where Mr. Teall completed the survey of these oldest rocks. As far as the mapping of the north-west Highlands has advanced, the various crystalline rocks older than the Torridon sandstone, and comprised under the general designation of Lewisian gneiss, may be divided into five distinct groups. (1) What has been termed the "fundamental complex," consisting of various more or less banded and foliated rocks which form together the oldest, and chief part of the gneiss. (2) Highly basic dykes cutting the fundamental complex. (3) Dykes and sills of dolerite, epidiorite, and hornblende-schist. (4) A few dykes of peculiar composition. (5) Gneissose granite, and pegmatite.

Mr. Teall has devoted himself, both in the field and with the microscope in the office, to the patient study of these rocks, and he has at last been able to formulate his views regarding the nature and composition of the various rocks comprised within the first of these sub-divisions, the "fundamental complex." He reports to me that over the greater portion of the area between Skye and Cape Wrath the rocks of the "fundamental complex" have decided affinities, both as regards chemical and mineralogical composition with plutonic igneous products, and his detailed Report, so far as these rocks are concerned, is now fairly complete. They are essentially composed of olivine, hypersthene, augite (including diallage), hornblende, biotite, plagioclase, orthoclase, microcline, and quartz; and the laws of paragenesis are the same as those which govern the composition of peridotites, gabbros, diorites, and granites. It is rare to find any one petrographical type persistent over a large area. Variations in the relative proportions of the different constituents are almost everywhere recognisable, and these variations may be either abrupt or gradual. One general law appears to have been established as far as the fundamental complex is concerned. Whenever the relative ages of two distinct petrographical types can be clearly ascertained, the more basic is older than the more acid.

In classifying the rocks, either with reference to structure or composition, difficulties arise in consequence of transitions in various directions. Many schemes have been proposed; and the following one, based primarily on mineralogical composition, and to a subordinate extent on structure, has been devised by Mr. Teall for descriptive purposes. Theoretical considerations have been excluded, and it is hoped that whatever view may be finally adopted, the broad general facts will be found to have been correctly recorded:—

I. Rocks composed of ferro-magnesian minerals without felspar or quartz.

(1) Pyroxenites.
Locality. Scourie, Drumbeg.
(2) Hornblendites.
Same localities as pyroxenites, and also as lumps in the gneiss of many other localities.

II. Rocks in which pyroxenes are the dominating ferro-magnesian constituents. Felspar always present, and in some cases quartz.

(*A*) Without quartz.
(*a*) Hypersthene-augite-rocks.
(1) With garnet (pyroxene-granulites).
Locality. Scourie.
(2) Without garnet (rocks of the Baltimore-Gabbro type).
Locality. Scourie, Gruinard.
(*b*) Augite-rocks. Gabbros in structure and composition, but forming part of the fundamental complex, and often associated with quartz-bearing rocks of a similar character.
Locality. Kyle Sku, Loch Inver.
(*B*) With quartz.
(1) Augite gneiss.
Locality. Kyle Sku, Loch Inver.

III. Rocks in which hornblende is the dominating ferro-magnesian constituent.

(*A*) Without quartz, or containing it only in small quantity. Rocks basic in composition.
(*a*) Rocks massive or only slightly foliated (Amphibolites).
(1) Epidote-amphibolite.
Locality. Near Stoer.
(2) Zoisite-amphibolite.
Locality. Sangomore Bay.
(3) Garnet-amphibolite.
Locality. Between Scourie and Laxford Bridge.
(*b*) Rocks foliated:—
Hornblende schist.
Locality. Between Laxford Bridge and Durness, also at Shieldag, Rona, and many other localities.
Note.—Many of the hornblende-schists found in the Lewisian gneiss are foliated dykes.

(*B*) With quartz. Rocks intermediate or acid in composition.
(1) Rocks with compact hornblende and a granular structure. Hornblende-gneiss (proper).
Locality. Between Laxford Bridge and Durness, Poolewe, Rona, Raasay, and many other localities.
(2) Rocks with hornblende occurring in fibrous or other aggregates:—
Locality. Between Scourie and Loch Inver, especially found in the same area as the augite-gneisses.
(3) Rocks with compact hornblende, and a more or less granulitic structure. Granulitic hornblende-gneiss.
Locality. In zones of secondary shear about Loch Inver.

IV. Rocks in which biotite is the dominating ferro-magnesian constituent. Felspar and quartz both present.

(1) Biotite occurring as independent plates or in aggregates of two or three large individuals. Biotite-gneiss (proper).
Locality. Between Laxford Bridge and Durness, Rona, Raasay, and many other localities.
(2) Biotite occurring in aggregates of numerous small individuals.
Locality. Associated with the augite-gneisses. A rare type.
(3) Biotite occurring as independent plates. Structure granulitic.
Locality. In zones of secondary shear.

While mapping the Lewisian gneiss of Raasay, Mr. Teall observed some curious patches of breccia in that island. One of these descends vertically into the Torridon sandstone, another occupies a similar position in the gneiss. The breccia consists of fragments of Torridon sandstone cemented with calcite, from which small rhombs of clear Iceland spar may be obtained. In one instance where the outlines of the breccia can be more distinctly traced, the ground plan of the mass is nearly semicircular, as if the breccia formed a plug in the Torridon sandstone.

Some interesting additions have recently been made to our knowledge of the Cambrian rocks of the north-west. Mr. Horne has found a band of fossiliferous ironstone, about two feet thick, in the "Fucoid beds" above Auchnashellach Station. The seam is full of a small discinoid or linguloid brachiopod. Mr. Macconochie has renewed his search for fossils in the *Olenellus*-zone, and has obtained additional specimens not only from the localities above Loch Maree and near Dundonnel, but from other outcrops of the same zone further to the north. He has detected fragments of trilobites together with other fossils of the same horizon on both sides of Loch Broom near Ullapool. He has likewise found them where the "Fucoid beds" appear in the River Achull, the Allatryne Burn, Strath Kaniard, Drumrunie and Knockan. Still further north Mr. Peach has obtained fragments of *Olenellus* from the same horizon at Inchnadamph. The ironstone-bed with brachiopods just referred to has been recognised by Mr. Macconochie in Glen Logan and other parts of

the Loch Maree district. It is thus shown that the "Fucoid beds" contain the fossils of the *Olenellus*-zone from the River Carron in Ross-shire to Loch Assynt in Sutherland.

An important addition to the evidence that tends to connect the quartzites and their associated strata of the south-western Highlands with those of Sutherland and Ross, has been obtained in the island of Islay. Reference was made in the last Report to the occurrence of worm-tracks in the dolomitic shales of that district which so greatly resemble the characteristic "Fucoid beds" of the north-west Highlands. Twenty specimens of tracks and burrows from the Islay shales have been obtained by Mr. Macconochie, and perhaps it is not too much to hope that eventually some of the other more distinctive fossils of the *Olenellus*-zone may yet be detected there.

In further prosecution of his mapping of the ground between Loch Carron and Loch Alsh, Mr. Peach has obtained additional confirmatory evidence of the view expressed in the last Report that the "Moine-schists" of that region are mainly altered Torridon sandstone and shale. These strata and their floor of Lewisian gneiss, which is occasionally brought up along sharp folds to the surface, are increasingly metamorphosed as they pass to the eastward.

Not less suggestive is the evidence recently obtained by Mr. Horne during his survey of the mountainous ground between the head of Loch Carron and Loch Maree. To the east of the great line of dislocation known as the Glen Logan or Kishorn thrust-plane, as in the ground south of Loch Carron, lenticles of Lewisian gneiss, brought up on the axes of isoclinal folds, occur among the Torridonian rocks, the whole series dipping in an easterly direction. That these long narrow exposures of gneiss are part of the actual floor on which the sedimentary formations rest, is proved by the occurrence of the basal Torridonian epidotic grits resting upon them. By means of this readily recognisable zone of grits and the shaly group that overlies them, it is not difficult to map out each separate isocline and to follow both the succession of the rocks and the structure of the ground.

As we advance eastwards, this metamorphism becomes more marked, the peculiar type or structure of the Moine or eastern schists coming out more and more clearly. It is difficult to understand that any other explanation of the sections can be adopted than that which obviously presents itself on the ground, namely that rocks having every character of true Moine schists, have here been produced by the alteration of a portion of the lowest Torridonian grits and shales with infolded cores of Lewisian gneiss.

Mr. Hinxman, working in that part of Strathspey which embraces the districts of Rothiemurchus, Abernethy and the ground between the Spey and the Dulnan, west from Aviemore, has met with a large tract of biotite-granite, similar to that of the Cairn-Gorm range, to which he proposes to give the name of Monadhliath granite, since it forms the eastern border of the Monadhliath mountains. He has ascertained that in this area, though the granite is fringed with abundant apophyses which penetrate the gneiss to distances varying from a few feet to 300 yards, no fine-grained edges indicative of the chilling of the intruded granite are to be seen. The injections of eruptive material have usually taken place along the planes of foliation, and the bands or planes of granite tend to branch out into mere strings. Besides the apophyses that can actually be traced into the main body of granite, many sills, bands or lenticular veins of similar material, may be seen in the gneiss immediately around the granite, and doubtless emanating from it. All the granitic bands, sills or veins, whether visibly proceeding from the granite mass or not, are thoroughly granitoid in texture and sometimes markedly pegmatitic. Not only do they present no chilled margins, but their crystals may be seen to interlock with those of the surrounding schists. Hence in this area there appears to be no reason to doubt that the present crystalline condition of the schists is coeval with the crystallisation of the material of the granite veins. The evidence, so far as it has at present been collected, appears to point to two conclusions. First, that the granites of Cairn-Gorm, Monadhliath, and other parts of Strathspey, together with most, if not all, of the sills and veins of granite and pegmatite in that region, belong to the same granitic protrusion and are derived from the same magma. Second, that this granitic magma has been protruded into a series of holocrystalline schists and quartzites, and that the contact metamorphism thereby superinduced, gave rise to the highly granulitic biotite-gneiss with bands of quartzite, which now forms the prevalent rock of the whole region.

In Deeside, Mr. Barrow has ascertained that the great granitic mass south of Banchory presents a very different character. The granite becomes rapidly finer in grain towards its margin, where it assumes the compact texture characteristic of a granite injected among already cooled rocks, while its apophyses are finer in grain than the main body of the rock. Of older date than this eruption is the granitic material, composed of microcline, quartz, and brown mica, which, in a vast number of narrow dykes or veins traverses the highly crystalline schists of the south side of the Dee.

The age of the red sandstones which extend along the eastern shore of Arran from Corrie to Brodick and thence across the southern half of the island, underneath the various sheets of eruptive rocks, has been much discussed. By Sedgwick and Murchison these strata were classed as New Red Sandstone, a view that was subsequently adopted also by Ramsay. Afterwards, however, Bryce and other writers placed them in the Carboniferous system, and correlated them with the red sandstones of the north of Ayrshire and Renfrewshire. A re-examination of the ground was made last spring by the Director General in company with Mr. Peach and Mr. Gunn. They found that pebbles of the Carboniferous limestone with its characteristic fossils actually occur in the breccias at the base of these red sandstones between Corrie and the north end of Arran, as was first observed some years ago by Mr. James Thomson. Closer inspection of the coast-sections and of the interior showed that, besides this evidence of a decided stratigraphical break, the red sandstone, conglomerates and breccias lie unconformably on the Carboniferous formations, though at the actual junctions the two series seem almost conformable. That they are probably Permian may be inferred on two grounds. In the first place, the lower group of false-bedded brick-red sandstones presents the closest resemblance to the red sandstones which, within sight on the opposite mainland of Ayrshire, rest upon the Coal-measures, and have been referred to the Permian period. In like manner, they resemble the red sandstones of the south of Ayrshire, Wigtonshire, and Dumfries-shire, which are also assigned to the same period. In the second place, the Arran red sandstones have been found by Mr. Gunn to enclose a contemporaneous volcanic group, a feature which is specially characteristic of the Permian series of the centre of Ayrshire, and of Nithsdale. The occurrence of *Stigmaria* in the volcanic series which lies some hundreds of feet above the base of the red sandstones seems to remove these strata from the New Red Sandstone or Trias, while the strong lithological resemblance which, both as regards their sedimentary and volcanic components, they present to the Permian series of the mainland opposite, renders it highly probable that they are Permian.

Mr. Woodward has mapped separately in Skye, as he did in Raasay, the passage-beds between the Upper Lias and the Inferior Oolite, which include shaly layers, and bands and concretionary masses of calcareous sandstone. These strata in Raasay yielded *Ammonites variabilis;* while in Skye they have afforded a form identified by Messrs. Sharman and Newton as *Ammonites Siemensi*, indicative of the zone of *A. jurensis. A. Murchisonæ* occurs in the lower part of the Inferior Oolite, and many examples of *A. humphriesianus*, and other fossils, not yet determined, have been obtained from the fine cliffs between Bearreraig Bay and Invertote. The upper portion of the Inferior Oolite does not appear to be fossiliferous on this Skye coast. It contains some shaly, and lignitic bands, and concretionary masses of sandstone, differing to some extent from the mass of white sandstones so prominent on this platform in the eastern cliffs of Raasay.

The Tertiary dykes of Skye are now being mapped, both on the north-east and south-east coasts. In the latter area Mr. Clough finds them to vary petrographically between the two extremes of pitchstone on the one side and troctolite on the other. Those of acid or intermediate character on the coast north of Loch-na-Daal often indicate the direction of flow of the molten rock in the fissure, by the elongation of the amygdales and the orientation of the rows of spherulites. From the variation in the positions of these structural lines, it is clear that the movement of the lava was by no means always vertical, but was often approximately horizontal or oscillating between the two directions. Records of the variations observed are being kept by Mr. Clough.

III. *Ireland.*

In pursuance of the work described in the last two Reports, Messrs. Kilroe and McHenry have during the past year advanced over a large tract of the difficult ground between Clew Bay and a line drawn from Clifden to Oughterard. Evidence obtained by Mr. Kilroe leads to the conclusion that the Croagh Patrick quartzite and its equivalent further south does not belong to the "Dalradian" series, but is a part of the Llandovery formation. It will thus be necessary to colour as ordinary Silurian a considerable tract of ground which has hitherto been regarded as composed of metamorphosed rocks. The rocks have undergone a certain amount of metamorphism, but never enough to destroy the clear evidence of their original clastic character.

The investigation by Mr. McHenry of the tract of ground between Clifden and Oughterard has resulted in the collection of a body of evidence which seems to disprove the existence of any Archæan rocks, at least within the area examined. What have been supposed to be rocks of that early age are believed by Mr. McHenry to consist of a complex series of intrusive masses which have pierced the schists, limestones and quartzites of southern Connemara. His survey during last year in that region has convinced him that the whole of these rocks, igneous and sedimentary, are the equivalents in age and petrographical character of the eruptive and metamorphic (Dalradian) rocks of Mayo, Sligo, Leitrim, Donegal, and other parts of Ireland.

Early in March the Director General took the opportunity to make with Mr. Peach and Mr. McHenry an examination of some of the ground around Pomeroy in Tyrone, where there seemed reason to believe that evidence might be found of the occurrence of a marginal strip of Lower Silurian rocks like those which have now been found to flank the southern border of the Scottish Highlands. On a former occasion he had observed among these rocks a remarkable group of basic lavas and tuffs, but could see no evidence to warrant their separation from the chloritic schists to the north of them. Recent mapping along the borders of the Scottish Highlands, however, having shown that a similar group of rocks in that region could be recognised as probably of Lower Silurian age, it seemed desirable that the Tyrone district should be re-examined. The result has been so far highly satisfactory. In company with Mr. Peach, who has also visited the Scottish localities, the Director General spent some days in traversing the Tyrone sections, and had no difficulty in recognising the close similarity of the rocks there exposed to those along the Highland border. The igneous rocks form a strip of country about twenty-four miles long with a maximum of nine miles in breadth, lying between the Silurian and Old Red Sandstone rocks on the south, and the crystalline schists on the north. They include diabase and porphyrite lavas, tuffs, and intrusive sheets. The lavas are interleaved with cherts and jaspers exactly like those associated with the igneous rocks at the edge of the Highlands. Apparently overlying the volcanic masses come dark shales, which might yield graptolites, likewise pale grits and occasional thin limestones. In Scotland the cherts enclose *Radiolaria*, and though these organisms were not detected in any of the Tyrone sections on the occasion of this visit, it may be confidently anticipated that they will be found on further and more detailed search. The radiolarian cherts of the Highland border, with their lavas and tuffs, appear to be a prolongation of those which with the same characters lie in the Arenig formation of southern Scotland, where they extend over a wide area. The importance of the discovery of a zone of Arenig rocks along the edge of the schists in the Highlands and in the north of Ireland will be obvious to all those who have followed the discussion regarding the structure and age of these crystalline schists.

While engaged in the preparation of the "Handbook of the Survey Collections," Mr. Watts had occasion to make many critical examinations of the rocks in the cases of the Museum. Among the new facts which this investigation has established, the following may be noticed:—The wide extent of lamprophyres in the north of Ireland; the occurrence of perlitic cracks in the quartz of the Tardree rhyolite; the remarkable replacement of olivine by tremolite, which eventually develops into idiomorphic crystals in the picrite of Glendalough; the intergrowth of biotite and hornblende in the Crossdoney granite, and the contact metamorphism around that rock.

Among the pebbles in the Drift of the east of Ireland, pieces of a granophyre, with the mineral riebeckite, are not infrequent. Prof. Sollas has been fortunate in finding for the first time one of these pebbles which contains true crystals of the mineral. He has found them to possess well-developed faces, and has been able to measure and describe them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. W. B. Prowse, of Pembroke College, has been elected to the Burdett-Coutts Scholarship in Geology, and Mr. R. M. Brydone, of New College, was awarded the scholarship which was not given last year, tenable for one year only. The Burdett-Coutts Scholarship is of the annual value of £115, and is tenable for two years.

CAMBRIDGE.—On November 4 the two vacant fellowships at St. John's College were filled up by the election of Mr. F. F. Blackman and Mr. S. S. Hough, late scholars of the College. Mr. Blackman is Demonstrator of Botany in the University, and took a first class in both parts of the Natural Sciences Tripos. Mr. Hough is Isaac Newton Student in Astronomy, and was Third Wrangler and Smith's Prizeman. Both of the newly-elected Fellows have communicated important memoirs to the Royal Society. Mr. Blackman's researches on the respiration of plants were referred to with high commendation by Mr. Thiselton-Dyer in his presidential address to the Botanical Section of the British Association.

The choice of the electors to the Professorship of Botany, vacant by the death of Prof. Babington, fell upon Dr. Marshall Ward, F.R.S., late Fellow of Christ's College, Professor of Botany at the Royal Engineering College, Cooper's Hill. Prof. Marshall Ward graduated B.A. in 1879, taking a first class in the Natural Sciences Tripos.

The State Medicine Syndicate report that, in view of the increasing importance of the study of bacteriology in relation to public health, they have decided to extend the time given to the subject in the Sanitary Science Examination, and to appoint a fifth Examiner specially conversant with it. Thirty-one candidates received the Diploma in Public Health in the last academic year.

The skeleton of a Chillingham bull has been presented to the Museum of Zoology by the Earl of Tankerville.

THE Report of the Royal Commission on Secondary Education has at last been published. The Commission was appointed in March 1894, "to consider what are the best methods of establishing a well-organised system of Secondary Education in England, taking into account existing deficiencies, and having regard to such local sources of revenue from endowment or otherwise as are available or may be made available for this purpose, and to make recommendations accordingly." The Report is divided into four parts, referring respectively to (1) previous legislation on the subject; (2) the state of things now actually existing; (3) the evidence submitted to the Commissioners, with a discussion of the views and suggestions of certain leading witnesses; (4) recommendations calculated to bring about that correlation of existing agencies and economical application of existing funds, which are required for the proper organisation of Secondary Education. Technical Education is included in the term Secondary, and the suggestions in the Report refer to both alike.

DR. FRANZ KÖNIG, Professor of Surgery in Göttingen University, has been elected successor to the late Prof. von Bardeleben in the Chair of Surgery at Berlin. Dr. Joseph Disse, of Halle, has been appointed Professor of Anatomy at Marburg. Mr. Frank H. Constant goes to Minnesota University as Assistant-Professor of Structural Engineering, and Mr. H. Wade Hibbard as Assistant-Professor of Machine Design. Dr. Partheil, of Marburg, has been appointed Professor of Pharmaceutical Chemistry at Bonn.

A FREE library, comprising museum, art galleries, and four branch libraries, has just been opened at Pittsburg. The erection of the institution has taken three years, and the cost—£200,000—has been defrayed by Mr. Andrew Carnegie.

MR. CECIL SMITH has gone to Athens to take up the Directorship of the British School there.

SCIENTIFIC SERIALS.

American Journal of Science, October.—Recent progress in optics, by W. Le Conte Stevens. This paper was read before the American Association, and gives an admirable summary of Michelson's work with the interferential comparer, of Wiener's experiments with stationary light waves, of recent researches on luminescence, and other subjects.—The quantitative determination of perchlorates, by D. A. Kreider. The method is essentially the collection of the oxygen of the perchlorate; its subsequent passage into an atmosphere of nitric oxide over a strong solution of hydriodic acid, and the titration of the iodine thus liberated with decinormal arsenic in alkaline solution. The apparatus employed consisted of a piece of combustion tubing, 10 or 12 cm. in length, drawn out at one end and connected with a receiver filled with caustic potash. A platinum boat carried the perchlorate, which was covered with a mixture of sodium and potassium carbonates. The tube was then filled with carbonic acid, and then the oxygen was evolved by fusion. The oxygen was swept by a current of CO_2 into a receiver consisting of two levelling bottles. For the action of the oxygen on hydriodic acid through the medium of nitric oxide, a bulb pipette was used with stopcocks at both ends. This was filled with a known amount of hydriodic acid, and the air expelled by CO_2, after which it was exhausted and a small quantity of nitric oxide was admitted. Then the oxygen was allowed to enter slowly under the diminished pressure, while the bulb was constantly shaken. It was then removed for titration.—Demonstration of caustics, by R. W. Wood. A strip of thin polished steel is bent into an arc formed by pins stuck on a board. A piece of cardboard is placed across the opening of the arc, and slits are cut in it about half an inch apart. A piece of photographic sensitive paper is stuck on a board inside the arc. On directing the apparatus towards the sun, parallel rays are traced from the slits to the mirror, and also their reflections, and the latter form the caustic surface appropriate to the curvature of the mirror.—The law of electromagnetic flux, by M. I. Pupin. The author endeavours to show the exact position which this law occupies in Maxwell's electromagnetic theory; to point out its limitations; to show that Maxwell's electromagnetic theory of light demands a more general form of this law; and to present a general form of this law of which the forms given up to the present are special cases.

American Meteorological Journal, October.—Fog signals and meteorology, by Prof. H. Hazen. The author discusses the penetrating power of various signals, the conditions under which fog is formed, and the effects of the winds and topography upon the audibility of the signals. He considers that, apart from the facts that a sound can be heard about twice as far with the wind as against it, and can be heard farther from an elevation than at the level of the sea, there is hardly a point which is well established. Also that the evidence points very strongly against the use of sirens or trumpets in any but a few exceptional cases where a very long range is demanded. A perplexing difficulty, referred to by the late Prof. Henry, arises from the fact that the signal often seems to be surrounded by a belt, varying in width from one to one and a half miles, from which the sound appears to be entirely absent. He considers that there is urgent need for a series of experiments from a rock or very low island, with open water for ten miles on all sides. Such experiments would probably elucidate many of the perplexing phenomena which now exist.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 16.—Prof. Meldola, F.R.S., President, in the chair.—The President announced the deaths of Prof. C. C. Babington, F.R.S., the last but one of the original members of the Society, and Prof. C. V. Riley, one of the ten Honorary Fellows of the Society, and commented upon their scientific work. Mr. W. F. H. Blandford spoke at some length on the valuable services rendered by the late Prof. Riley to the cause of economic entomology, and referred to the enormous number of papers and memoirs on the subject which he had contributed. Lord Walsingham, F.R.S., also spoke as to the importance of the late Prof. Riley's work and the respect and regard which he felt for his estimable personal qualities.—Mr. F. C. Adams exhibited a series of nineteen *Merodon equestris*, containing several varieties, showing their resemblance to wild bees of the family Apidæ, and made a few remarks on mimicry. He also exhibited specimens of *Leptomorphus walkeri*, Curt., taken in the New Forest in September last, and *Melanostoma hyalinatum*, Fln. (male and female), also taken in the New Forest in the latter part of August last. Mr. Verrall, Dr. Sharp, F.R.S., and Colonel Yerbury made some remarks on the species and their distribution.—Mr Enock exhibited, and made remarks on, specimens of the mature male and female, and the nest of *Atypus piceus*, the British Trap-door spider; also male and female specimens of *Andrena atriceps* and males of *A. fulva*.—Mr. Tutt exhibited a long series of 143 males and 25 females of *Erebia nerine*, captured in the Tyrol, partly in the Mendel Pass and partly in the Val d'Ampezza, and read notes on the species, in which he criticised the description of it, and the published observations as to its habits, by Dr. Lang, Mr. Elwes, and others. Mr. Elwes made some remarks in reply.—Lord Walsingham exhibited the type of *Pseudodoxia limulus* (Kghfr.), together with the larval cases and a preserved larva. He directed attention to the curious truncate concave head of the larva which forms an operculum to the tube, and remarked that the cases of this insect, which were apparently not uncommon in Ceylon, the larva feeding on mosses and lichens, had been known for some considerable time. So long ago as 1864, Mr. McLachlan found them in the British Museum collection of cases of caddis worms, and at that time, being only acquainted with the case, he was disposed to consider them the work of one of the *Leptoceridæ*. In 1889, Herr Rogenhofer gave the name *Fumea* (?) *limulus* to the case and its contents, and Mr. McLachlan agreed from the evidence then adduced that the insect was *Lepidopterous* rather than *Trichopterous*.—Mr. C. J. Gahan exhibited, for Mr. Turner, an imago and some larval forms of *Ledra aurita*, Linn.—Mr. G. C. Griffiths exhibited, and read notes on, hybrids between *Platysamia cecropia* (male) and *P. gloveri* (female), and between *P. cecropia* (male) and *P. ceanotha* (female); also between *Actias luna* (male) and *A. selene* (female). He stated that these hybrids were bred by Miss Emily L. Morton, of New Windsor, New York, in 1891, 1892 and 1893.—Lord Walsingham stated that at the last meeting of the Society some discussion ensued, after the reading of his paper, in consequence of his having alleged that *Grapholitha*, W., was preoccupied by *Grapholitha*, Hb. (Verz. Schm.), and he read a supplementary note on the subject explaining the references in his paper.—Dr. A. G. Butler communicated a paper, entitled "Notes on seasonal dimorphism in certain African butterflies."

PARIS.

Academy of Sciences, October 28.—M. Marey in the chair.—The Associates and Correspondents of the Academy are invited to send their photographic portraits to the Secrétariat to form part of a projected album.—Lord Kelvin read an address from the Royal Society of London, and then expressed his appreciation of the honour conferred upon him by his election as a Foreign Associate of the Academy. In his speech he referred to France as his *Alma mater* in science, and mentioned his personal connection with Regnault in 1854 at the Collège de France.—On the multiple roots of algebraical equations, by M. Brioschi.—On the differences of longitude between Nice, Ajaccio, and Rousse Island, by MM. Hatt, Driencourt, and Perrotin. A telegraphic determination in which observations have been carried out between different pairs of observers, and checked by comparing the longitude of Ile Rousse determined from Nice with the longitude of the same place determined from Ajaccio, which itself had its longitude compared directly with that of Nice. The direct determination of the difference in longitude of Ile Rousse and Nice gave 6m. 34·45s. ± 0·01s. Indirect determinations gave 6m. 34·442s. ± 0·019s., and 6m. 34·465s. ± 0·017s.—M. Armand Gautier presented the second volume of the second edition of his "Cours de Chimie," and described the points in which it differed from the first edition.—General A. de Tillo presented and described a relief map of the western part of Russia, and the bordering parts of contiguous States.—On chemical equivalents, by M. Marqfoy. The author enunciates the following as a law of chemistry, and supports it by tables printed in the abstract: "The actual equivalents of chemistry are the prime numbers comprised in the natural series of whole numbers from 1 to 300." He adds that he has established the constitutive theory of substances based on the unity of matter. He introduces *porosity* into the consideration of volumes, and asserts that he thus overthrows Dulong and Petit's law, and Avogadro's hypothesis. The author has found the following

law to hold: "The specific heat multiplied by the density equals the porosity, the porosity of hydrogen at the given temperature and pressure being taken as unity."—Observations of the comet 1895, August 20, and of Wolf's planet (1895, October 13) made at Toulouse observatory with the great telescope, and the 0·25 m. equatorial, by M. Rossard.—On the double diurnal oscillation of relative humidity, by M. Alfred Angot. It is shown that the phenomena described by M. Éginitis in a recent number of the *Comptes rendus*, is due to sea-breezes, and has been noticed previously. It does not occur in continental stations, on plains or plateaux.—Observation of an electric phenomenon, by M. Mettetal. A description of an electric fire-ball observed in stormy weather, but in the absence of thunder and lightning, at Grenoble, on October 2. The phenomenon vanished without detonation.—Researches on lithium, magnesium, and cuprous cyanides, by M. Raoul Varet. A thermochemical paper giving the heats of formation of these cyanides. It is pointed out that there is not the same parallelism between the cuprous and cupric cyanides as obtains with the mercurous and mercuric salts.—On beryllium carbide, by M. Louis Henry. The author calls attention to the weakness of M. Lebeau's argument for assigning the atomic weight 14 to beryllium, and recapitulates the considerations which have determined the acceptance of 9 as its atomic weight by most chemists.—On the analysis of emerald, by M. P. Lebeau.—On the estimation of argon, by M. Th. Schlœsing, jun. The author discusses the errors inherent in the method lately described by him, and gives results of the estimation of argon in air taken at different times and from different places. The amount found is constant at 0·934 per cent. Gases from soil show some variations in the amount of contained argon, possibly due to the solubility of this gas.—Synthetical formation of a new ketonic acid, by M. E. Burker.—On the muscles of ants, wasps, and bees, by M. Charles Janet.—On the development of nerve terminations (neuromuscular junctions and motor plates) in striated muscular fibres, by MM. G. Weiss and A. Dutil.—Liquefaction of gelatine, saline digestion of gelatine, by MM. A. Dastre and N. Floresco.—Researches on the biological value of inflammatory leucocytosis, by M. Wladimir Woronine. Localised inflammatory leucocytosis is peculiar to vertebrates, and is an accidental consequence of the particular conditions occurring in their system of blood circulation. Leucocytosis is not a purposed defence against an enemy which has penetrated the organism, as the phagocyte theory maintains. The modifications which are common to all the cases studied are not aggressive, but passive.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 7.

LINNEAN SOCIETY, at 8.—On Mimicry in Butterflies of the Genus Hypolimnas, Hübn.: Colonel Swinhoe.—A Revision of the Genus Pentas, Benth.: G. F. Scott Elliot.—An Account of the Butterflies of the Genus Charaxes, Ochs.: Dr. A. G. Butler.

CHEMICAL SOCIETY, at 8.—The Temperatures of Flames and the Acetylene Theory of Luminosity: Prof. Smithells.—The Action of Acidic Oxides on Salts of Hydroxy-acids: Prof. G. G. Henderson and D. Prentice.—Sodium Nitrosulphate and the Constitution of Nitrosulphates: Profs. Divers and Haga.—And other Papers.

FRIDAY, NOVEMBER 8.

ROYAL ASTRONOMICAL SOCIETY, at 8.

PHYSICAL SOCIETY, at 5.—The Magnetic Field of any Cylindrical Coil or Plane Circuit: W. H. Everett.—The Latent Heat of Volatilisation of Benzene: Mr. Griffiths and Miss Marshall.—The Comparison of Latent Heats of Volatilisation: Prof. Ramsay and Miss Marshall.

SUNDAY, NOVEMBER 10.

SUNDAY LECTURE SOCIETY, at 4.—What Man can obtain from the Land: Prince Kropotkin.

MONDAY, NOVEMBER 11.

ROYAL GEOGRAPHICAL SOCIETY, at 8.—Progress of the Jackson-Harmsworth Arctic Expedition: A. Montefiore.

TUESDAY, NOVEMBER 12.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Colour-Correct Photography and a New Plate: James Cadett.—Note on the Sensitiveness of Picrated Gelatine to Light: W. K. Burton.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—The Customs and Habits of the Natives inhabiting the Bondee Country: Rev. Godfrey Dale.

ROYAL VICTORIA HALL, at 8.30.—Mountaineering in Central Africa: Dr. J. W. Gregory.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Address by Sir Benjamin Baker, K.C.M.G., President, and Presentation of Medals, &c.

THURSDAY, NOVEMBER 14.

MATHEMATICAL SOCIETY, at 8.—On the Stability and Instability of certain Fluid Motions, iii.; and on the Propagation of Waves upon the Plane Surface separating Two Portions of Fluid of different Vorticities: Lord Rayleigh, Sec.R.S.—Note on Matrices: J. Brill.—Determination of the Volumes of certain Species of Tetrahedra without employment of the Method of Limits: Prof. Hill, F.R.S.—Some Algebraical Theorems connected with the Theory of Partitions: Prof. Forsyth, F.R.S.—Certain General Series: F. H. Jackson.—An Extension of Sylvester's Constructive Theory of Partitions: Major MacMahon, F.R.S.—Note on the Representation of a Conic by a Linear Equation: J. Griffiths.—On the Representation of a Number as a Sum of Squares: Prof. G. B. Mathews.—Theories of Magnetic Action upon Light: A. B. Basset, F.R.S.

FRIDAY, NOVEMBER 15.

EPIDEMIOLOGICAL SOCIETY, at 8.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—An Exercise Book of Elementary Practical Physics: R. A. Gregory (Macmillan).—Statically Indeterminate Structures and the Principle of Least Work: H. M. Martin (*Engineering* Office).—Mensuration for Senior Students: Prof. A. Lodge (Longmans).—Milk, its Nature and Composition: Dr. C. M. Aikman (Black).—British and European Butterflies and Moths: A. W. Kappel and W. E. Kirby (Nister).—Physiology: Dr. A. MacAlister (S.P.C.K.).—The Structure and Development of the Mosses and Ferns: Prof. D. H. Campbell (Macmillan).—Toxin: "Ouida" (Unwin).—Die Artbildung und Verwandtschaft bei der Schmetterlingen: Dr. G. H. T. Eimer, ii. Theil (Jena, Fischer).—Ethnische Elementargedanken in der Lehre von Menschen: A. Bastian, 2 Vols (Berlin, Weidmann).—North American Shore Birds: D. G. Elliot (Suckling).—Practical Physiology of Plants; F. Darwin and E. H. Acton, 2nd edition (Cambridge University Press).—Hints on the Teaching of Elementary Chemistry in Schools and Science Classes: Prof. Tilden (Longmans).

PAMPHLETS.—Mirifici Logarithmorum Canonis Constructio: J. Nepero, facsimile reprint (Paris, Hermann).—Die Überwindung des Wissenschaftlichen Materialismus: Prof. W. Ostwald (Leipzig, Veit).

SERIALS.—National Review, November (Arnold).—Quarterly Journal of the Geological Society, Vol. li. Part 4, No. 204 (Longmans).—Contemporary Review, November (Isbister).—Quiver, November (Cassell).—Natural Science, November (Rait).—Fortnightly Review, November (Chapman).—Imperial University, College of Agriculture Bulletin, Vol. 2, No. 4 (Tōkyō).

THE EVOLUTION OF THE COSMOS.

Notes on the Nebular Theory in relation to Stellar, Solar, Planetary, Cometary and Geological Phenomena. By William Ford Stanley, F.R.A.S., F.G.S., &c. (London: Kegan Paul, Trench, Trübner, and Co., Limited, 1895.)

THE object of the present treatise is to establish in a modified form the nebular theory of Laplace, by the introduction of some original views which have long occupied the attention of the author. This is an ambitious scheme, and it is a little disquieting to read that authorities whose opinions carry weight did not recommend the communication of these views to the learned societies, whose duty it would have been to weigh and consider them. The reason assigned is, that the views were thought to be too speculative; and after studying them with great attention, we have no hesitation in saying that we hold the advice to have been sound.

Undoubtedly the nebular hypothesis as enunciated by Laplace is on its trial, and does not recommend itself unreservedly to those most capable of judging its merits. It may be admitted that a new working hypothesis would demand and receive great attention. But emendations, to be accepted, must come from those who have made a profound study of mathematical and physical science, and have proved themselves men of original genius. It may be that Mr. Stanley has qualified himself to speak with authority on this difficult subject, and undoubtedly the many references quoted in his volume display considerable reading and research; but the references are too frequently, not to original sources, but to the more popular writings and expositions to be found in the *Proceedings* of the Royal Institution, or in the pages of *Good Words* or the *English Mechanic*, and these authorities are quoted, apparently with as much satisfaction as the *Philosophical Transactions*. It is impossible to resist the impression that the author's scientific information is second-hand. The literary style of the work does nothing to remove this impression, and is incompatible with a complete mastery over the subject. Clearness of expression is wanting; obscure passages, that tax the patience of the reader, abound, and occasionally we come across sentences that defy interpretation altogether. As an example of these latter, we may give the following (p. 42):—"Assuming the pneuma to be a most perfect fluid and elastic system of matter, upon the meeting of two volumes of such matter, independently of any initial rotation it might possess, must have moved under pressure at the meeting plane in every or any direction, which at the time offered the least resistance to the continuity of its initial momentum." Obscurities such as these may possibly prevent the presentation of the author's views exactly as he would have wished. There are many statements which we cannot accept, if we have properly understood them, but which, expressed differently, might command a ready assent.

At the outset of his work, Mr. Stanley gives an historical account of the distinguishing features of the main cosmical theories, which have been elaborated by great minds in the past. The author's want of grasp and poverty of description are in this first chapter most conspicuous. Instead of a full and lucid account of these earlier ideas, which one would naturally expect in a work of this character, the reader must be content to find very meagre and obscure notes on the theories of Descartes, of Kant, of Laplace, or of more modern authorities, as Helmholtz, or of Faye. From this point onward to the end of the book, the author devotes himself to the description of his own views and theories. It has always been admitted, hitherto, by scientific men, that nothing more than a partial solution of the problem presented by the origin of the universe can possibly ever be expected, and, certainly, that our present state of knowledge is inadequate to the task. Laplace, for instance, based his hypothesis on the assumed existence of the sun, and sought to prove no more than the possibility of the formation of a system of planets, such as we see in existence. Mr. Stanley's theories are far more ambitious. Not only does he seek to account for a state of things existing prior to, and leading up to the formation of the sun, but he undertakes to explain such details as geological periods and the disposition of the materials of the earth's crust.

Following the theory which was first suggested by Wright of Durham, that the Milky Way forms one vast originally connected system, Mr. Stanley imagines immense districts in space filled with matter in its "original state." This is assumed to be of an attenuated gaseous character, and since the calculated size of the ultimate atom would leave less than a single specimen to the cubic metre, each one, for reasons which are not apparent, is divided into a large number of parts called "pneumites," which in a state of perfect atomic dissociation give rise to every line in the spectrum of light. The form of the "pneumites" is described in detail; but, inasmuch as our knowledge of the ultimate nature of the atom itself is confessedly imperfect, these speculations are obviously useless from a scientific point of view.

Having formed these arbitrary notions of the elementary condition of matter, existing at a high temperature, Mr. Stanley proceeds to explain the origin of the Milky Way as a vast agglomeration of pneumites, to which he gives the name "pneuma," moving in slow rotation. To account for the flattened form of the Galaxy, it is suggested that two such spheroidal "pneumas" drifted together at an early period, forming at their common surface a somewhat denser plane, over which the more distant parts of the pneumas would spread themselves by the action of their original momenta, while such parts as did not entirely combine would cause an apparent bifurcation. The division of this original "pneuma" system into nebulæ, and ultimately stellar systems, appears to be left to no more dignified cause than chance, aided by condensations brought about by heat radiation. The means by which it is suggested that these bodies kept distinct can only be described as obscure and unsatisfactory, and the attempt to cover with a false appearance of reasoning what must, by the nature of the case, remain matter for the vaguest speculation and assumption, is altogether to be regretted.

The author proceeds to discuss the behaviour of one of these separate condensations which is taken as the

origin of the solar system. It is limited in every direction by the surface at which particles are in equilibrium under the influence of gravity of the solar nebula itself, and of the nearest stellar systems. Under the pressure of the outer portions, a centre of greater density would be formed, to which would be attracted all the matter in the inner parts of the nebula. The outer parts, on the other hand, condensing by radiation, as it is suggested, into comets and meteorites, will not reach the vicinity of the solar nucleus until a much later period, depending on their distances. Some of these will fall into and augment the nebulous sun, while others will become permanent members of the solar system. It is typical of the author's method that either event is left entirely to chance, and it is difficult to see where a line is to be drawn between the sun-forming matter and that which evades the nebulous envelope of the central attracting body. The abrupt disruption of the nebula, thus introduced, offers a most perplexing difficulty.

The process by which the planets come into existence presents precisely the question, to which an answer would be expected in the book before us. It must be said at once that the portion of the book dealing with this question is most unsatisfactory. In addition to the obscurity of style, to which allusion has already been made, the unfortunate arrangement of the subject-matter makes it quite impossible to gain any clear insight into the author's views as a connected whole. Mr. Stanley appears to adopt the theory of Laplace in its main features, not because he has any novel arguments to urge in its support, nor on account of the reasons which have hitherto led to its tentative acceptance, but because, in his opinion, no other theory heretofore offered possesses any reasonable probability. "Nevertheless," he says (p. 65), "it is not probable that our system was formed by any simple single mechanical effect of the action of forces upon surrounding universal matter, as generally assumed in special theories, but rather that all possible conditions were active, that may have conspired to produce the final results." Thus, for example, according to the theory of Laplace, the author thinks there should be a simple relation connecting the masses of the planets with their respective distances from the sun. He therefore attempts to explain the irregularities observed in the masses of the planets, by supposing them to be caused by the precipitation into the solar nebula of that matter, which at a much earlier period condensed by itself at the outermost parts of the solar "pneuma." Such a process implying the previous formation of masses, of variable amount, and operating irregularly and intermittently, may account for the existence of planets greatly differing in size; but, at the best, the difficulty is only removed from one place to another. It seems equally impossible to agree with the author that the plane in which the planets revolve, has been determined by the superior attraction of the two nearest stars. For both this plane and the equatorial plane of the sun should apparently preserve the direction impressed by the moment of momentum of the original solar nebula.

Space will not permit us to follow further Mr. Stanley's notions of the processes of planetary evolution or the effects which, it is suggested, the successive formation of planets had upon geological periods. It can only be said that the author toys with millions of years in a manner which possibly amused himself, but which can scarcely be edifying to the serious student. Unless the leading points of Laplace's theory can be placed practically beyond question, the consideration of details can have no scientific interest. And Mr. Stanley could hardly expect to rescue from its present position of doubt, and to place on a secure basis a theory, on the merits of which the ablest mathematicians and physicists have been unable to arrive at a definite conclusion. We have already intimated our opinion that the author's knowledge of mathematics and physics is slight. In confirmation of this view, we might draw attention to his treatment of the problem of finding the volume of a ring (p. 82), and to a bold assertion, on p. 190, concerning the increase of vapour tension in the atmosphere. We might, too, point to his contemptuous rejection of the theory, well supported by the highest authority, that the interior of the earth is not fluid. He is also singularly unhappy in refusing to accept Prof. G. Darwin's demonstration, that the earth formerly rotated at a much higher velocity than at present, because the study of the effects of tidal friction has always appeared to give direct evidence in favour of the probability of the nebular hypothesis.

W. E. P.

ELEMENTARY HIEROGLYPHICS.

First Steps in Egyptian: a Book for Beginners. By E. A. Wallis Budge, Litt.D., Keeper of the Egyptian and Assyrian Antiquities, British Museum. (London: Kegan Paul, Trench, Trübner, and Co., 1895.)

A REVIEW of a book dealing with the laws and structure of language may perhaps at first sight appear out of place in a journal devoted to science. A moment's consideration, however, will convince the reader that the book, the title of which stands at the head of this column, may be regarded as an exception to the rule. Very little was known of ancient Egypt until, at the beginning of the present century, the genius of Young and of Champollion led to the decipherment of the native inscriptions. Since that time, however, Egyptology has attracted many workers, and to the results that have followed the first decipherment the student of anthropology is perhaps even more indebted than the philologist; for while the language in itself proved unattractive in conquence of its somewhat chaotic structure, the subject-matter revealed was of the very highest importance. The key to the hieroglyphics, in fact, admitted the anthropologist and man of science to the study of the legends and beliefs, the daily life and customs of a people, whose history commences more than four thousand years before our era.

The truth of this statement is confirmed by the immense mass of literature that has within the last few years grown up around the records and remains of ancient Egypt. The man of science has made good use of his rich vein of fresh material, histories have followed quickly on one another's heels, while many of the Egyptian sacred texts and legends have appeared from time to time in the form of short stories and translations; in fact, the public has been amply provided with the means for acquiring a general knowledge of Egyp-

tian science, history, and literature. But many people are not content to get their information entirely at second-hand. A winter spent in Cairo, or even a visit to a local museum, has perhaps tempted them to try to find out for themselves how the Egyptians recorded the legends and history of which they had read, or wrote down the prayers and ritual of which they had seen translations. Few, however, have found it easy hitherto to satisfy their curiosity, for the standard grammars and dictionaries of the language, with which the trained Egyptologist works, are either too costly or too stiff for the beginner, while editions of texts generally presuppose a knowledge of the language, and in many cases must be unearthed from the journals of learned societies. It is not surprising, therefore, to find that many a beginner has been discouraged by the great outlay, both of time and money, that must precede the commencement of his studies.

To any one who has had this experience, we would recommend Dr. Wallis Budge's "First Steps in Egyptian." Here the beginner who is anxious to tackle for himself the interpretation of Egyptian hieroglyphics, and to control the statements of scientific or popular writers, has the means placed at his disposal between the covers of a single book; and, should he subsequently wish to continue his studies, he will find himself enabled by its help to use with advantage the more advanced grammars he may come across in English, French, or German. A brief description of its contents will serve to indicate its general scope and character.

The book consists of two parts—the first containing an introduction, the second the texts. In the former, Dr. Budge begins by dismissing in a few paragraphs the external aspect of the subject, briefly referring to the history of Egyptian decipherment, and describing the manner in which inscriptions are written; he then passes to a detailed explanation of the twofold functions performed by the hieroglyphic signs, as ideographs and phonetics, and appends a list of the common signs with their phonetic values; the function of determinatives is next explained, and their use illustrated by a number of examples. The reader is then in a position to appreciate an analysis of an extract from a text, and an explanation of the methods by which its meaning may be ascertained. The rest of the introduction deals successively with pronouns, nouns, the article, adjectives, numbers, measures, divisions of time, the year, the verb, the adverb, prepositions and conjunctions, and particles, in each section of which any rule or statement is illustrated by a number of examples, and concludes with a list of common words and a list of the names of Egyptian gods and goddesses. Part ii. contains a series of some thirty texts and extracts, ranging from the Third Dynasty to the reign of Ptolemy V., and these are followed by a few untransliterated and untranslated texts, which the reader is intended to work out with the help of a short glossary at the end of the book.

In his selection of texts we think the author has been wise to look out for passages interesting in themselves, for by this means the reader's attention is secured. The translations of some of the shorter extracts are well worthy of quotation, some of the "Maxims of *Ani*," for instance, inculcating a lofty morality, while others show a shrewd knowledge of the world. "Take to thyself a wife while she is young, and she will make for thee thy son." "The time [once] past, one seeketh to grasp others [in vain]." "Enter thou not among the many, that thy name may not stink." "Answer thou not an angry master; speak that which is soft while he is uttering that which is of wrath." "Festal cries are abhorred by the sanctuary of God. Make thou supplication with a loving heart, its petitions being all in secret, and He will perform thy affairs, He will hear that which thou sayest, He will receive thy offerings." "Do not put thyself into the house of drinking beer. An evil thing are the words reported second-hand coming forth from thy mouth, thou not knowing they have been said by thee. Having fallen, thy members are broken, another giveth not the hand to thee. Thy companions [in] drink stand up, saying 'away with this drunkard.'" "Death cometh; it seizeth the babe which is on the breast of his mother as well as him that hath become an old man." "[When] thy messenger [of death] cometh to thee to carry thee off, be thou found by him ready." We have not space to do justice to the varied selection of historical and religious texts here collected, but may refer the reader especially to the quaint legend of "The Destruction of Mankind," and to *Tuauu-f-se-Kharthai's* humorous praise of the literary life and its rewards, in which he contrasts it with the unattractive trades of the blacksmith, "who stinketh more than the eggs of fish"; of the barber, "who worketh violently by his two arms to fill his belly"; of the weaver, "who is more wretched than a woman, whose legs are under him at the door of his heart, who breatheth not the air"; of the dyer, "whose fingers stink [with] the smell of the keeper of dead bodies"; and of the shoemaker, "who is the most unfortunate of all, for he chattereth everlastingly . . . [and] feedeth upon leather." We will conclude with a few lines from one of the untranslated texts, the touching address to the deceased lady *Ta-khert-p-uru-abtu*, which may be summarised as follows:—

"O thou triumphant one! thy soul liveth in heaven with the god Rā. Thy *double* has had offerings made to it among the gods. Thy beatified form is glorious among the shining ones. Thy house is filled with children and a husband, who as they follow thee weep. Thy children are rewarded by meeting thee for all they have done to thy *double*. Thou hast been buried rightly and gloriously, and they have placed thy *double* at the west of Thebes, opposite thy fellow-citizens. Thy tomb shall never be ravished, thy bandages shall never be stripped off, and thy body shall never suffer harm. Thy soul flieth towards heaven to meet the soul of the gods. . . . Thy life shall endure for ever, thy majesty shall be eternal, and thou shalt enjoy an endless number of festival-cycles, each of which shall endure for 120 years!"

It must not be supposed from what we have said that the book opens up a royal road to knowledge. No new language can be acquired without continuous work and perseverance, and Egyptian is far from being an exception to the rule. Hitherto, however, in addition to encountering the actual difficulties of the language, the beginner has been handicapped by a long and often unsuccessful search for his materials; his first steps, in fact, were unnecessarily arduous, and in making these more easy Dr. Budge will have deservedly earned his gratitude.

THE CLASSIFICATION OF ROCKS.

An Introduction to the Study of Rocks. By L. Fletcher. (British Museum (Natural History) Mineral Department, 1895.)

HAVING received from the facile pen of Mr. Fletcher a guide to the Mineral Gallery of the British Museum, and an introduction to the Collections of Minerals and Meteorites which it contains (works of a very high order from their simple lucidity as well as their thoroughness and accuracy) the student has looked forward to a companion work on the Rock Collection, from the same writer. This work has now made its appearance, and is no whit behind its fellows in outward aspect, being printed in clean, clear type, on good white paper, cheap, not too bulky, and attractive in its general appearance.

A large part of the work is taken up with an essay on classification, which will certainly tend to impress the student with the care that must be used in seizing on essential characters, the numerous pitfalls to be avoided, and the necessity of employing every instrument of research available in the study of rocks. After some preliminary paragraphs on the varied points of interest which rocks present; on the chief characters presented by the two constituents of rocks, minerals and amorphous matter; and on their ordinary modes of origin; the author observes that rock-masses vary so much from point to point, that "similarity, not identity" of characters can alone be aimed at in a classification. He strives to recognise the existence of "*petrical individuals*," but, owing to variation in different parts, to alteration, inclusion, and denudation, fails to reach the ideal, and is compelled to state that "petrical individuals have rarely, if ever, existed." We can hardly realise, however, that the inclusion of fossils or pieces of foreign rocks, which seem to trouble the orderly mind of the author, can have any real bearing on nomenclature; a boy is no less a boy if he happens to have swallowed a button. The outcome of this discussion is that "a rock-name is only required by the mineralogist for the purpose of indicating the *kind* of rock, not the particular rock-mass itself."

An admirable account is then given of "lithical characters" observed in hand specimens, both in relation to their individual constituents and to their aggregation or structure, and of the "petrical characters," which are only to be observed on a large scale in the field. A very useful term is here introduced—"merocrystalline," which is to be correlative with holocrystalline; all petrologists will be grateful for this substitute for semi-crystalline and the other unsatisfactory terms that they have been compelled to employ under protest. Taking the characters here specified, the author employs them to construct a tentative classification of a set of typical rocks, by linking into one group those which have several of these important characters in common. The first scheme attained by this method is in part natural, in that it brings together those "rocks which are composite in kind of material, holocrystalline, and without directional lithical characters," such as granite, syenite, diorite, dolerite, and euphotide. But it is also in part artificial, as, for instance, when it brings together gneiss, shale, and slate because they possess directional characters, and coal, clay, and phonolite because they are compact though composite. Mr. Fletcher points out that "directionality has been useful, however, in enabling us to bring together the rocks belonging to the several kinds"; but that things thus wedded are to be so quickly divorced is, we take it, his method of enforcing the necessity for most careful selection of essential characters in classification. The primary essential, when hit upon, turns out to be mode of origin.

From this point things go more smoothly, and the rocks fall into a grouping which is, for the most part, natural; want of complete knowledge on such subjects as the origin of the crystalline schists still, however, leaves us in difficulties in classifying these rocks, and we are compelled to place in an artificial group many which differ widely in their methods of origin.

In developing the natural grouping finally adopted, the history of the granite and basalt controversies is succinctly told, and a set of useful definitions and descriptions of the chief types of rocks is given. The work closes with a brief syllabus of these types, which have, through the devious course of trial and error, at last found rest in natural and fairly well-defined groups.

OUR BOOK SHELF.

Facts about Processes, Pigments and Vehicles; a Manual for Art Students. By A. P. Laurie, M.A., B.Sc. (London: Macmillan and Co., 1895.)

IN the majority of cases when a student of painting has seriously entered upon his work in a school of art, he has no wish, he makes no attempt to investigate the chemical and physical properties of the materials he employs. He is content to copy the practice of his teachers and fellow-learners; facility in working and immediate effectiveness are all he demands. He may even go so far as to resent the intrusion of science into the domain of art. To ask a painter to study exhaustively the chemistry of the materials and processes of painting would be unreasonable, for a whole-hearted devotion to the prime business of his life must be his first concern. Nor can an adequate grasp of the difficult and varied problems offered by pigments and vehicles and painting-grounds be acquired by listening to a few lectures, witnessing a few experiments, and reading a few chapters in a manual. The author of the little book before us makes a very modest demand upon the time and patience of the student of painting. Here are no symbols and formulæ to repel the uninitiated, no tables of constants, no complex theories of reaction and change. Mr. Laurie's readers are first furnished with a set of easy experiments which have been devised to show in an obvious way the nature and treatment of the chief pigments and vehicles. Then, in part ii., some notes on methods of painting in tempera, fresco, water, and oil are given, while the volume concludes with a glossary of pigments and a list of the chemicals and apparatus needed for carrying out the experimental work described in the earlier chapters of the book. There is one section of the volume which seems somewhat incongruous—a description of "drawing for process" and an endeavour to estimate the artistic value of the leading methods of photographic reproduction. Mr. Laurie will doubtless effect some improvements in a second edition—a little more attention to literary style is desirable. The late Mr. Gambier Parry of Highnam Court would have been surprised to find himself described as French. There are, indeed, very few slips or errors in this little volume—very few statements and explanations with which the writer of this notice does not agree.

A. H. CHURCH.

Practical Proofs of Chemical Laws: a Course of Experiments upon the Combining Proportions of the Chemical Elements. By Vaughan Cornish, M.Sc. (London: Longmans, Green, and Co., 1895.)

THIS small work is essentially a product of the modern efforts to teach science by a scientific method.

The author has endeavoured to give, in some ninety-two pages, clear and sufficient instructions for the experimental verification of the great quantitative laws upon which chemistry is based, and he has fully succeeded.

Nothing could be better calculated to lend interest to the work than the author's plan of quoting the results which were considered sufficient to establish these laws in the early days of our science; and the comparison of experimental data, obtained by the student, with the classical results of the great pioneers of chemistry, must lend a reality and zest to his efforts.

Used in its proper place, with students who have been well trained in general experimental science, and under the supervision of a capable teacher, there is no reason to suppose that the somewhat dogmatic statement of chemical laws will have any ill result.

The statement of the law of constant proportion given on p. 3—"this proportion remains constant in compounds which contain also other elements"—is so worded as to convey a wrong impression. It might be thought, for instance, that the proportion obtaining between potassium and chlorine in potassium chloride would remain the same in potassium chloroplatinate, which contains also another element platinum, and a reference to chapter v. would confirm this impression. It is evident that this statement requires remodelling.

Certain slips of a different type have found their way into the text. Thus, "*hollow glass-rod*" is mentioned on p. 52; and on p. 62, it is advised to treat silver with "pure strong hydrochloric acid" in order to convert it into silver chloride. Notwithstanding these minor defects, the book may be safely commended as embodying a well-thought-out and feasible plan of work. T.

Great Astronomers. By Sir Robert S. Ball, F.R.S. Pp. 372. (London: Isbister and Co., 1895.)

THE greater part of this book consists of *réchauffées* articles from *Good Words* and other publications. At the present day there is a large public curious to know biographical details, so no doubt the book will find many appreciative readers. The astronomers whose lives are portrayed are Ptolemy, Copernicus, Tycho Brahe, Galileo, Kepler, Newton, Flamsteed, Halley, Bradley, William and John Herschel, Laplace, Brinkley, the Earl of Rosse, Airy, Hamilton, Le Verrier, and Adams. It need hardly be said that the serious student of astronomy will find little in this book not already familiar to him; the volume is intended for the popular mind, and therefore much of it is small talk of the kind in which the general public revels. When the lives of eighteen astronomers are described in a volume of less than four hundred pages, as they are in this book, it is needless to say that only a few of the features characteristic of each can be presented. Sir Robert Ball has, however, selected the chief features in the lives and works of the great men who form his subjects, and his sketches, though verbose in parts, bring to light a few new facts in which astronomers generally will be interested. The book contains numerous illustrations, many of them new. The illustrations chiefly represent the astronomers described, and their houses, observatories, and instruments. We cannot understand, however, why some of them are in the book at all; for instance, with the sketch of the Earl of Rosse we find pictures of Birr Castle; The Mall, Parsonstown; and the Roman Catholic Church at Parsonstown. The connection of these views with "Great Astronomers" is much less reasonable than that between cats and clover.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Sir Robert Ball and "The Cause of an Ice Age."

I SHOULD like to correct one statement in my long letter in NATURE of October 17. I there said that Sir Robert Ball had not withdrawn his claim to the discovery of the law of distribution of summer and winter temperature in each hemisphere, which had in fact been previously published by Wiener. I am reminded by Mr. Kendall that I had overlooked a second edition of the book in which credit is duly assigned to Wiener. Thereby hangs a tale. I have looked in vain through Low's well-known list for any trace of a second edition. I also looked through the British Museum Catalogue without any result, and inquired in the Copyright Office in that establishment, and was told that no such book had reached the Museum. Lastly, the Museum people tell me they have applied to the publisher for the book, and have received the reply that it is only a re-issue, and not a new edition with new matter in it.

I am further told by the Museum officials, that he has thereby incurred a penalty of £5 for non-compliance with the Copyright Act. It was by an oversight of his, therefore, that this second edition has been overlooked by myself and, probably, by others.

In this second edition, Sir R. Ball, after unwittingly wearing the nimbus for six years, gives up his oft-repeated claim to be the discoverer of the law in question, and attributes it to Wiener. As the publication of his discovery was the alleged reason for writing the book, he had now to find another excuse, and did so by reiterating the unjust accusation he had made against Croll of having ignored the disparity between the sun-heat of summer and winter, and thus necessitating the writing of a work to set the world right on the matter.

As long ago as 1891, Mr. Noble had called attention to this injustice, and shown that Croll had nowhere made the mistake attributed to him, and quoted passages from pages 55 and 86–7 of "Climate and Time," to show that he was perfectly aware of the real conditions. Although Croll nowhere cites the actual numbers 63 and 37, or 3·93768 and 2·34550 as Wiener gives them, it is odd that in calculating the amount of sunshine received at Edinburgh in summer and winter respectively, he does give the numbers 7 to 4, that is, 63 : 36, and "Climate and Time" was published four years before Wiener's "Memoir."

It is quite true that Croll does not use these figures in his calculations as Dr. Ball does. For him they would be mere academic numbers, since he knew, as we know, that the problem to be solved depends much on the proportions of the differential temperature of different latitudes at different seasons, and little or nothing on the proportions of the temperatures at different seasons of a whole hemisphere lumped together.

Since the above was written, Mr. Hobson has replied to my previous note, complaining that I have converged attention upon the now famous law, which was supposed to be Sir R. Ball's own child, and have not referred to the effects of varying eccentricity, which were everybody's property. He forgets that I was criticising Dr. Ball, who habitually claims the law in question as the *causa causans* of an Ice age, and especially refers to this invariable and constant factor as "the following theorem which constitutes *the essence of the astronomical theory of an Ice age.*"

The value of this essential factor of the problem being the matter in dispute, I presume Mr. Hobson wrote his letter to illuminate your readers, and not merely to engage in a profitless polemic. If so, perhaps he will do me the favour of meeting the following case.

(1) Wiener's law is not disputed. It represents the proportions between the *sum* of all the sun-heat received in either hemisphere in summer and winter respectively.

(2) Sir R. Ball makes it apply not only to the whole hemisphere, but to different zones in the hemisphere, and notably to Britain (see "A Cause for an Ice Age," new edition, pp. 127–131). Will Mr. Hobson support this astounding conclusion?

(3) In the zone between the tropics there is perpetual summer, and it absorbs one-half of the sun's heat received on the earth in equal proportions in the two seasons. Here, therefore, the proportions of sun-heat are not 63 : 37, but 50 : 50. There-

fore Wiener's law is not true of this zone taken apart. If we subtract the sun-heat received in this zone where glacial conditions never existed, we shall find that the proportions in the temperate and polar zones combined are not 63 to 37, but 38 to 12. So that Wiener's law is not true of these zones where glacial conditions alone existed. If, instead of taking the tropics, we take the area limited by the parallels of 45°, which is a better boundary for the district displaying glacial phenomena, the disparity is still greater. At Edinburgh, as Croll long ago said, the proportions are about 3 to 1. Does Mr. Hobson dispute this?

(4) Dr. Ball nowhere connects Wiener's law as a cause with the Glacial age as an effect *by proof of any kind*. He merely offers us certain *obiter dicta*, and argues that if the present proportions of sun-heat were distributed over a winter of 199 days and a summer of 166 days, we should have a glacial climate in Britain. Since the proportions of sun-heat actually recorded in Britain at this moment in our 199 coldest and 166 warmest days respectively show a far greater disparity than that represented by these figures, I may, I think, ask if Mr. Hobson admits this *reductio ad absurdum* of Sir Robert Ball's argument to be valid?

(5) Lastly. For the first time, Mr. Culverwell has applied numerical tests and methods to the problem of discovering the actual and not the hypothetical results on climate caused by a varying eccentricity of the earth's orbit. He has done so by comparing the actual sun-heat received by each latitude now, and contrasting it with the actual sun-heat received by the same latitude in the time of greatest eccentricity, and has shown that the limits of variation do not amount to more than can be measured by removing a parallel of latitude from 3½ to 4 degrees. This to some of us is absolutely conclusive, not only against Dr. Ball's arguments, but against all astronomical theories, including Croll's.

The real point and meaning of my letters is that in regard to the astronomical theory of an Ice age all the kind of reasoning employed by Sir R. Ball and its consequences are fallacious. They have been swept away and shown to be worthless by Mr. Culverwell's method of solving the problem, which is inductive and decisive, and which rigorously proves that Sir Robert Ball's results are as extravagantly baseless as his method is unfruitful. This being so, it is most clearly incumbent upon the Lowndean Professor either to answer his accomplished critic or to withdraw his book, which is only misleading the unwary by having its mistaken and shattered arguments sheltered under the Astronomical Chair at Cambridge. It ought certainly to have no place in a series entitled "Modern Science," where ascertained results and not ingenious fallacies ought to find a place. Nor ought Mr. Kegan Paul's name to appear on its title-page as a guarantee of its scientific soundness.

The Athenæum Club, October 29. HENRY H. HOWORTH.

Curious Aerial or Subterranean Sounds.

PROF. G. H. DARWIN, in NATURE for October 31, p. 650, asks for information as to the "Barisàl guns." The name is derived from Barisàl or Burrisal, a town in the eastern part of the Gangetic delta, and the best and most recent account of the sounds known as the "Barisàl guns" is to be found in the report of a sub-committee of the Asiatic Society of Bengal, published in the *Proceedings* of that Society for 1889, p. 199.

The great difficulty in the way of accepting the suggestions of Messrs. Meldola and Davison (NATURE, November 7, p. 4), that earthquake shocks are the cause of the sounds, is the restriction of the "Barisàl Guns," so far as is known, to a comparatively small area, where earthquakes are of rare occurrence, and to a particular season of the year.

W. T. BLANFORD.

[*Translated by Prof. G. H. Darwin.*]

AN article, by Prof. G. H. Darwin, on "Barisàl Guns and Mistpouffers" appeared in NATURE for October 31. Summarising a letter in which I drew his attention to this phenomenon, he mentions two sources for these mysterious sounds, which my friend M. Rutot and I have considered as possible, namely that the origin is entirely terrestrial, or that it is a special phenomenon of atmospheric electricity. It is as well, perhaps, also to point out another purely atmospheric source, viz. that it may arise from the abrupt displacement of a mass of superheated air in unstable equilibrium, which rises suddenly in the atmosphere.

This was the explanation given to M. Lancaster by the late M. Houzeau, the astronomer, on the former sending him my first notes on this phenomenon, in about 1881. M. Houzeau also stated that he had himself observed the noises, but that he could not suggest any more plausible explanation than the above.

In confirmation of this hypothesis, I would remark that *this year* the mysterious detonations were heard up to the end of September, and even up to the beginning of October, not only by me but by several of my friends and correspondents; this is much later in the year than usual. Now great and unusual heat prevailed this year during the whole autumn, and this coincidence affords a strong support to the theory of an origin arising from certain conditions of rise of temperature.

Sailors of the port of Ostend assert that "Mistpouffers" prevail over the whole of the North Sea as far as Iceland, and they consider them to be a sign of fine weather, with calms and heat.

The mysterious noises, mentioned to me by Mr. Clement Reid, which are heard on Dartmoor and in Scotland near the Highland Fault, are not perhaps exactly comparable with "Mistpouffers"; for Mr. Reid writes to me that these sounds are probably associated with those incessant tremors of the earth's crust, which are well known in these districts. With respect to sounds of this peculiar kind, readers of NATURE will find an interesting note by Mr. Charles Davison, entitled "On Earthquake Sounds," in the *Geological Magazine* for May 1892.

I might add many interesting data concerning "Mistpouffers," but I have promised to reserve them for the Belgian magazine *Ciel et Terre*, edited by M. Lancaster. In that journal, the readers of NATURE who are interested in this subject, will shortly find a complete account of the papers which have come to my knowledge; to which they will doubtless be able to add a number of facts and observations, which will prove of great service for the scientific study of the question.

ERNEST VAN DEN BROECK.

39 Place de l'Industrie, Brussels.

I HAVE heard many queer noises in lonely spots, and wish I had made note of the time and place and circumstances. But though I have few exact facts and figures, I have a very distinct recollection of many such observations, some of which are a direct answer to the question asked by Prof. Darwin in your number of October 31, while others seem to have a bearing upon it.

I have sometimes heard on the mountains north of the great Craven Faults, from which I looked over low ground towards Morecambe Bay, what I always took to be the sound of heavy guns somewhere out seaward. They were not, however, repeated at such intervals, nor for so long a time as to support the view that it was the sound of artillery practice; and, when I made inquiries from friends who resided in the district, I never learned that there was anything of the sort going on. The sound struck me as peculiar, but I could not find any satisfactory explanation of it. I considered many possibilities. First, there was the general question of the different transmission of such sounds according to the state of the atmosphere. Fog, for instance, affects it. In the particular case I have mentioned, I knew there were great quarries in various places within a few miles, and I had always before me the possibility of my having heard the sound of blasting echoed by some combination of cliffs to where I was.

The noises I heard were just such as are produced by the thud of the wave as it fills a cave. The muffled sound of the impact of water is heard a long way off. An idea of its force may be gained from cases in which the air, instead of being compressed in the hollow of the rock, finds an opening to the surface of the ground above, and rushes out, sometimes followed by a spout of spray. Its recurrence is irregular, and it lasts only for the short time when the rise and fall of the waves just fills and empties the cave. The direction of the transmission of this sound to long distances is still more uncertain.

In the case of the air-thuds on the Yorkshire Fells this explanation is extremely improbable, and the "guns of Barisàl," so named from the town and river of that name, boom across the flat delta of the Ganges, where there can be no cliffs or caves. What is really common to the two areas suggests another possible explanation.

The sound of the first blow of the curled wave upon the shore or on the sea, and of the outburst of the great volume of air included in its fold, is carried an immense distance. I have heard it much resemble heavy guns. It is exceptional and irregularly intermittent. It is only when the tide has reached one part of

the long, flat shore, that the right combination occurs. For, when there is a ground swell on, the waves do not roll in continuously, but come in groups, and therefore we require the coincidence of the higher waves and the right minute on the shore.

Now, Morecambe Bay has a long flat shore, over which the tide comes in so fast that it has been known to overtake a coach-and-four. It is open to the south-west wind and the Irish Channel tide. The time when the "Barisàl guns" are heard is when the great tidal wave is rushing up the estuaries in the Bay of Bengal. This is a very suggestive coincidence.

Before we go further in our investigation of air-thuds, it would be of great help if we would get some exact data as to the distance at which the sound of great guns, of blasting, or of waves, can be proved to have been heard. So far I have endeavoured to explain such sounds by surface action. I believe, however, so strongly in the rapidity and constant recurrence of earth-movements which must produce sound, that I would add a few words upon that point.

To begin with small sounds. When the sun is setting and the shadows of the mountain climb up the screes or talus, each part rapidly passes from sunshine into shade, and often into very cold shade. In such circumstances it is not uncommon to hear a crepitation among the fragments. This is quite in accord with the view that the downward travel of the screes is largely due to diurnal changes of temperature affecting the fragments of which they are composed. More rarely bangs are heard among the crags in similar circumstances. The ticking of the firedogs and iron-work of a grate when the fire has gone out, and the sudden and terrifying crack of the oak-wainscoted room, are familiar examples of the same kind of thing. In frost, of course, such noisy ruptures are common.

Now as joints in rocks are surface phenomena, due to shrinkage, detonations accompanying such disruptions should be often heard. Under the artificially-produced conditions of mining they are frequently heard. In the limestone quarry, from which the black marble of Dent is procured, the workmen found that, when they were quarrying the lower beds, and struck the rock with a pick or bar, fragments flew up into the air with a greater force than could be due to the blow of the pick, and in an unexpected direction. Also, when the tunnel was being made above Ribble Head, and the workmen were engaged upon the bed of rock which formed the floor of the tunnel, pieces used to burst off with a loud noise, so that some of them thought that they had discovered a detonating shale. The explanation in both cases was that the hard thin bed which shelled off in that unexpected manner, rested on compressible shale, which, behaving as a fluid, transmitted the pressure due to the sides of the quarry or the wall of the tunnel, squeezed up the floor where the rock had been removed, and produced what in a coal mine would be called a "creep." The thin bed of hard rock above the shale rose in a slight arch over the upthrust shale, and was thrown into a state of tension, so that, when it was struck, chips, flakes, and sometimes larger pieces, would fly off. Phillips pointed out that "the removal of one side of a vein would leave the remaining side in a condition of strain resembling that of a strung bow, with a tendency to bulge outward into the workings," and it is known that from such a surface, especially when covered with a coating of crystalline vein-stuff, fragments fly off with cracks and explosions of various degrees of intensity. Earth-movements and the action of subterranean waters are continually opening out channels in which all these processes which produce strained surfaces and consequent explosions are going on. The widespread belief that fairy or goblin miners are heard working deep in the bowels of the earth probably arises from these natural rock-burstings, which are, from the nature of the case, more apt to occur along the line of lodes. I have myself been advised to go in for certain mining speculations because the sound of workmen's tools had been heard beneath the ground.

As on a small scale along lines of tension, artificially or naturally produced, so on a large scale along the lines of strain due to the great earth-movements, which are continually going on, analogous disruptions must repeatedly occur. When it is on a great scale, and the tremors and throws accompanying it have been observed, it is called an earthquake; when the noise only of the break is heard, it is unrecorded, because of the difficulty of distinguishing one air-thud from another. It must be a phenomenon of not uncommon occurrence along the lines of more rapid earth-movement, for we must bear in mind in all such inquiries that time is an element in the bending of rocks. In the cases I mentioned above, it is the rapidity of the action due to the artificial removal of the mass that causes the rock to break rather than to sag or bend, and retain its curved form. This last we see commonly among the contorted strata where nature has applied the pressure more gradually; but we also see evidence of more sudden movement in faults and slickensides and similar phenomena, all of which are going on still, and must be accompanied by sounds could we only detect them.

T. McKenny Hughes.

Cactaceæ in the Galapagos Islands.

In my notice (Nature, p. 623) of Dr. Baur's botanical collections from the Galapagos Islands, I intended to add a few words respecting the Cactaceæ, but forgot it at the last moment. This natural order of plants forms the most conspicuous feature in the vegetation of some of the islands, as may be seen in the excellent views illustrating the cruise of the U.S. ship *Albatross*; yet Darwin, so far as I can discover, is the only naturalist who ever brought away any specimens, or contributed to any more exact knowledge than can be got from photographs on a very small scale. The presence and abundance of Cactaceæ in these islands is highly interesting, especially in relation to the age and origin of the flora, and to the fact that none exist in Juan Fernandez, though they abound in Chili. They are also of great importance to the animal kingdom during long droughts, as they are then the only source of water. As we learn from Darwin, the succulent branches are eagerly devoured by the large tortoises, lizards, and various other animals. He found that lizards four feet in length were easily enticed whenever he threw them a piece of a branch, and small birds would come within a few feet of him and peck at one end whilst a lizard was eating at the other.[1] Darwin also regarded the Cactaceæ as a source of food; and it is noteworthy that animals were mainly dependent on the branches broken off by wind. *Opuntia galapageia* was found by Darwin on James's Island, growing from six to ten feet high, with a trunk a foot in diameter, and so densely covered with strong spines as to be protected from destruction by predatory animals. The younger branches bear only long elastic bristles. Dr. N. J. Andersson, a Swedish botanist, who visited the islands in 1851, states (Eugenies Resa, "Botanik," p. 95) that this cactus grows in all the islands, and he adds that he observed at least four or five other species, but had not time to collect specimens or to sketch them. In another place ("Linnæa," xxxi., 1861–2, pp. 571–631) he particularly mentions the *Opuntia* growing in lava where nothing else would grow, forming huge candelabra-like objects with pretty red, shining fruits. It is evident, too, from the photographic views reproduced in the "General Sketch of the Expedition of the *Albatross*," that one (or more) species of *Cereus* attains a height of ten or twelve feet, and is equally prominent in the landscape. Perhaps the next botanist who visits the islands may find time to study the Cactaceæ. But when will any Government think it of sufficient importance to attach a really qualified botanist to such expeditions? I ought to add that Dr. Baur is not a botanist, but he appears to have done his best as a botanical collector.

W. Botting Hemsley.

Slow Lightning.

As far as I know, the first description of slow lightning occurs in your issue of November 7. It must be very rare, for I have never met any one who would readily believe in its existence. I write to testify to the accuracy of Mr. Crawford's description, though I have not seen it quite as slow as the flash which he timed. The best example that I ever saw was in a storm over London some eighteen years ago. "A thick stream poured down, in the sort of curve which liquid takes from a kettle, and was then slowly joined by a similar stream from the opposite direction, the united stream then continuing its slow course downwards. I was not where I could see the end of it. The peculiarities—the breadth of the streams, and their deliberate motion—could scarcely be an optical delusion. The streams did not appear to me as "chains."

I have observed lightning all my life, and since it has begun to be photographed, I have been looking out for pictures of the various types. I hope we may get some picture of this, and

[1] See *Magazine of Zoology and Botany*, i. (1837), p. 467, where Prof. Henslow describes and figures *Opuntia galapageia*.

also of the sheaf form, which I have seen in storms directly overhead, the flash being like two brushes discharging in opposite directions, recalling the classical representations of the lightning in the hand of Jupiter. ROBERT BRIDGES.

Yattendon, Newbury, November 8.

An Early Reference to Hydractinia?

IN Swammerdam's letter to Thevenot on the anatomy of the Hermit Crab, there seems to be a reference to Hydractinia. The passage ("Biblia Naturæ," Leyden, 1737, i. 197) runs thus:—"Maximas tamen omnes [conchas] *Fuci marini quædam species, punctis vel apicibus minutis assurgens*, obtegebat eousque; ut tota nonnullarum figura obscurata & deformata esset; neque spiralium, quibus gaudent, convolutionum ulla posset conspici."

I venture to suggest that the words in italics fairly (though, of course, not literally) correspond to the "chitinous crust covered with numerous grooved and serrated spines" of Hincks ("Brit. Hydroid Zoophytes," i. 23, 24). The obliteration by Hydractinia of the whorls of shells tenanted by the Hermit Crab is well-known. Specimens showing such obliteration may be seen in the Natural History Museum, South Kensington.

Harringay, N. HENRY SCHERREN.

Rooks and Walnuts.

MR. REID'S remarks on rooks carrying off acorns, suggests my mentioning that they are great depredators of my walnuts. They come early in the morning, attack the walnuts on the trees, and carry them off to an adjoining field, where they punch a hole in the shell and extract the contents.

They build on several groups of elms in Ealing, and on one row of trees close to Christ Church they come regularly at Christmas to see what repairs are required; but one tree, which has an electric wire running through it, they now entirely avoid.

GEORGE HENSLOW.

A Substitute for Sulphuretted Hydrogen.

HAS "Rusticus" (see vol. lii. p. 597) heard of liquefied H_2S? I have tried it, and find it works admirably. Unlike ammonium thio-acetate, it can be obtained from any of the usual chemical dealers; a bottle containing a pound, = 11 cubic feet, can be had for a few shillings. It is always on hand when required, and entirely dispenses with the old H_2S apparatus and its abominations. A very great desideratum is the purity of the liquefied gas. CHEMICUS.

A GERMAN IMPERIAL INSTITUTE.

IN his presidential address to the British Association at Ipswich, reported in NATURE on September 12, Sir Douglas Galton referred to the efforts made by the German Government and Municipalities to advance scientific knowledge and promote research. In his statement that the "Royal Technical High School" at Charlottenburg "casts into shade the facilities for education in the various Polytechnics which we are now establishing in London," he scarcely appreciates the radical distinction between the German and London institutions, which accidentally bear the same name, but which are wholly different in purpose and organisation. But his remarks on the Reichsanstalt of Berlin are so suggestive and so full of interest, that I was eager to have the opportunity of visiting the Institute, and was glad within the last week or so to be able, during a brief stay in Berlin, to make myself better acquainted with its work.

The Institute, as its name implies, is an "Imperial Institute," as distinguished from the Polytechnicum, which is under the Government of the Prussian State. The Polytechnicum, or Technical High School, has been already described in NATURE, and is one of a number of technical universities situated in the several States which compose the German Empire. The Berlin Institute at Charlottenburg is by far the largest and the most completely equipped in Europe, and is already pronounced too small for the ever-increasing number of students, now exceeding 3000. In close proximity to this building in the Marsch Strasse, a turning in the leading avenue through the Thiergarten, the Physical-Technical Imperial Institute is now being erected. When complete it will consist of three detached buildings, in addition to separate residences for the Director and for some members of his staff. Two of these buildings are already finished, but the third is not yet erected, and pending its completion the work of this section of the Institute is carried on in a portion of the basement of the Royal Polytechnic.

The work of the Institute consists of two separate, but in some respects associated, sections. Section I. is devoted to pure scientific research, and Section II. to the testing and standardising of different kinds of measuring instruments. The Research Department is already housed in the main building of the new Institute, which has been planned especially for the purpose; whilst much of the testing work of the other department is still carried on in the Polytechnic building. The united Institute is under the general direction of Dr. Kohlrausch, and is maintained at an annual cost to the Government of about £15,000.

The Research Department of this interesting Institute is housed in a three-storeyed building, consisting of a basement, a main floor, and an upper storey. The construction is in many respects peculiar. The walls, instead of resting on separate concrete foundations, are built into a concrete flooring two metres deep, which covers the entire area of the building, so that the walls, basement, and flooring are closely bound together. The effect of this is that the building, if it vibrates at all, must vibrate as a whole, and no one part is separated from another. There is consequently no need for the isolated pillars which are found in some of our English laboratories. But even this arrangement does not appear to be perfect, and although the building is well set back from the road, in which there is some traffic, vibratory movements are not entirely avoided. The principal floor of the building consists of a central room, used mainly for experiments requiring constant temperature, surrounded by a corridor which leads into a number of other laboratories for experiments in electricity, magnetism, light, and heat. There are various interesting arrangements for maintaining the constant temperature of the central room, including the admission of light from the top through a series of separated glass roofs. The experimental work of the first section, or "Abtheilung," is under the direction of three heads of departments, Drs. Thiesen, Jaeger and Lummer, who occupy themselves respectively with investigations in heat, electricity, and light. They are aided by a number of permanent assistants, and by other workers who are admitted into the Institute for the prosecution of some special investigation. The members of the staff are engaged entirely in research, and have no teaching duties. The researches of the staff during the past year comprise numerous investigations connected with the determination of the expansion of bodies under heat; experiments with different kinds of thermometers, and pyrometers; electric and magnetic investigations; and photographic and photometric experiments. Short notices of these researches, giving the results as ascertained, are annually published.

Section I. is occupied exclusively with the testing of different measuring instruments. The makers of thermometers, manometers, and pressure gauges of all sorts, send their instruments to the Institute to be tested. Galvanic elements, accumulators, arc lights, ammeters, electric condensors, resistance coils, &c., are being tested in different parts of the building. No measurements connected with weight or mass are undertaken, and the testing of the strength of materials for builders and engineers is carried on in other buildings in no way connected with the Institute. The number of thermometers alone sent to the

Institute to be tested amounted last year to 11,656, of which 10,005 were clinical thermometers. A small charge is made for work done for the trade, but the receipts from this source of revenue do not exceed £1000. Incidentally, in connection with this work, there is a large amount of original investigation, and the staff employed are all men of proved scientific ability. New methods for obtaining more correct results and greater accuracy in measurement are constantly being investigated, and to this extent Section II. is equally with Section I. a laboratory of research. The experiments in Section II., however, are all directed towards the more accurate testing of instruments of precision. Some of the work done in this section is undertaken at the request of the staff of the Research Laboratory, and in connection with the experiments in pure science.

This Imperial Institute is under the immediate control of a Curatorium or Council, consisting of Professors of the University and Polytechnic, of engineering and technical experts, and of heads of industrial firms, presided over by a member of the Government. The selection of members of the staff, and permission to work at the Institute, rest with the Council. At first, applicants for admission were required to have obtained their Doctor's degree; but no such rule now holds. The ability to work, and the intention of prosecuting some original investigation previously approved by the Council, is a sufficient qualification. Each application for admission is considered on its merits. The Physical-Technical Imperial Institute is the crown of the series of coordinated Institutions which afford facilities for technical instruction in physical science, and opportunities for advanced research. In the city of Berlin are well represented the various educational agencies which have contributed so largely to the greatness of Germany; and the improvements which have been made of late years in the lighting and sanitation, in the postal and telephone arrangements of Berlin, are so many practical indications of the value of the education which the State and the city jointly provide. The Physical Institute is literally a temple dedicated to science, and its two divisions correspond with the twofold character of all scientific work—that which is undertaken with the sole object of widening the area of knowledge, and that which enables knowledge to be applied to the useful purposes of life. PHILIP MAGNUS.

THE PLANET JUPITER.

THIS bright planet now rises more than two hours and a half before midnight, and as his northern declination is about 18⅛°, he attains an altitude of about 57° when southing at about 5h. 15m. a.m. His apparent equatorial diameter this evening (Nov. 14) will be nearly 40″·5, and is increasing daily, so that by the end of the year it will be 45″·6, when the planet will be visible nearly all night, and remain above the horizon during a period of 15½ hours. He will arrive at opposition to the sun on January 24, 1896, and will then be displayed under the best conditions.

To those, however, who are disposed to study the complex and variable features exhibited by the belts, the present is an important time, for it is advisable that such markings should be watched during long periods, and that a large number of their transits should be recorded. Their individual rotation periods may then be ascertained, and the differences determined, together with the fluctuations of speed affecting the same objects. Details of this character can only be correctly derived when the observations are numerous and extend, at least, over a fairly long period of time. Materials of the kind alluded to, obtained in the early part of the opposition, are of special value for comparison with the observations made at the time of opposition, and with the terminal ones which may be secured in the evenings of June 1896, just before the planet leaves us for a season.

The features of Jupiter, though liable to certain changes, are yet, in some of their leading characteristics, remarkably durable. Like the spots on the sun, many of the markings on the planet disappear and reappear under very similar aspects. In fact, we are not without evidence that a certain degree of periodicity regulates the visibility of certain spots on the disc. In 1870 there was an eruption of dark spots along a belt in about 25° north latitude. In 1880 the phenomena appear to have recurred, for the same belt became studded with black spots, and in 1891 similar appearances were repeated. These markings are remarkable, as possibly indicating a periodical recurrence at intervals of about ten or eleven years. But it may be gravely doubted whether, in the present state of our knowledge, the materials exist for suitably investigating the question as to cyclical changes in the Jovian spots. The individuality of observers must affect the matter to a considerable degree, as their drawings and descriptions of the same features are seldom in agreement.

In recent years, the great red spot has not been so much observed as formerly. It has lost its striking character and its novelty, and planetary students have somewhat neglected it for newer objects more readily within reach. During the last ten years the mean rotation period of the spot has been 9h. 55m. 41s.; but it has shown some irregular variations. The slackening motion of the spot which operated so perceptibly between 1879 and 1885, and added seven seconds to the rotation period, appears to have been checked in the latter year, and the rate has been pretty evenly maintained since that time.

As to the visible aspect of the spot, it is now extremely faint, and can only be discerned on a good night of definition. Its feeble outlines are generally lost amid the very dark and well-marked boundaries of the belts in its immediate vicinity. But on a good night it is seen as a pinkish discolouration of the bright zone outlying the great southern equatorial belt, though its beautiful oval outline is distinguished with difficulty.

One of the interesting features of recent oppositions of Jupiter has been the series of dark and white spots plentifully arranged along the northern side of the great northern equatorial belt. These markings move swifter than the red spot, but not much so, for their period is 9h. 55m. 35s., or only six seconds less. They show changes, for sometimes one may be seen exceedingly dark, if not absolutely black, and just like a satellite-shadow in transit; but in a week or two a great decadence of tone may have affected it, and it appears scarcely darker than the belt on which it lies. These markings, so prominently fringing the northern belt, have certainly been visible during the last ten years. In 1885 I found their motion about eight seconds swifter than that of the red spot, but there were irregularities. Different spots, though in the same longitude and, probably, of the same character, do not yield coincident times of rotation, nor does any one object maintain exactly the same rate during a long period of time. The current in which they are situated, and by which they are transported to different longitudes, evidently suffers inequalities of speed, which are probably due to local disturbances underlying it.

These features of the northern belt are still very pronounced. On the morning of September 27, I observed two very dark spots projecting north from the belt and preceding the red spot at intervals of about four and two hours. The red spot follows Mr. Marth's zero meridian (System II.) by about seven minutes, but I have only obtained two observations since Jupiter has been visible as a morning star, and neither of these was very satisfactory.

During ensuing months it will be important to make as many drawings as possible, and to secure a large number of transits of the various markings. Among others the following may be specially mentioned:

(1) Light and dark spots near the equator (period 9h. 50m. 6s. in 1880, increased to 9h. 50m. 30s. in 1888).

(2) Dark spots on a belt in latitude 25° + (period 9h. 48m. in 1880, increased to about 9h. 49½m. in 1891).

(3) Dark spots and breaks in a very narrow belt in latitude 35° + (period 9h. 55m. 39s. in 1895).

(4) Light and dark spots in the region south of the red spot (period 9h. 55m. 18s., and apparently unchangeable between 1880 and 1891).

In the course of his work, the observer will also detect other features worthy of attention.

From eye-estimated transits the periods of the various objects can be very accurately ascertained, and Mr. Marth's valuable ephemerides for physical observations of Jupiter, published in *Monthly Notices* (June and supplementary numbers, 1895), will assist the student to reduce his own materials. W. F. DENNING.

NOTES.

THE Royal Society's medals have this year been adjudicated by the President and Council as follows:—The Copley Medal to Prof. Karl Weierstrass, For. Mem. R.S., for his investigations in pure mathematics; a Royal Medal to Prof. James Alfred Ewing, F.R.S., for his investigations on magnetic induction in iron and other metals; a Royal Medal to Dr. John Murray, for his services to biological science and oceanography in connection with the *Challenger* reports, and for his original contributions to the same; and the Davy Medal to Prof. William Ramsay, F.R.S., for his share in the discovery of argon, and for his discoveries regarding gaseous constituents of terrestrial minerals. Her Majesty the Queen has been graciously pleased to approve of the award of the Royal Medals. The medals will, as usual, be presented at the anniversary meeting on St. Andrew's day (November 30). The Society will dine together at the Whitehall Rooms on the evening of the same day.

THE following is a list of those who have been recommended by the President and Council of the Royal Society for election into the Council for the year 1896, at the anniversary meeting on November 30:—President: Sir Joseph Lister, Bart. Treasurer: Sir John Evans, K.C.B. Secretaries: Prof. Michael Foster, the Lord Rayleigh. Foreign Secretary: Dr. Edward Frankland. Other members of the Council: Mr. William Crookes, Sir Joseph Fayrer, K.C.S.I., Mr. Lazarus Fletcher, Dr. Walter Holbrook Gaskell, Dr. William Huggins, the Lord Kelvin, Prof. Alexander B. W. Kennedy, Prof. Horace Lamb, Prof. Edwin Ray Lankester, Prof. Charles Lapworth, Major Percy Alexander MacMahon, R.A., Prof. John Henry Poynting, Prof. Arthur William Rücker, Mr. Osbert Salvin, Prof. Harry Marshall Ward, Admiral William James Lloyd Wharton, C.B.

THE Trustees of the British Museum have decided not to fill up for the present the Keepership of Zoology, vacant by Dr. Günther's retirement, but to appoint two additional Assistant-Keepers from the existing staff, so that there will be one for each of the three sections into which the department will be divided for administration purposes, viz. insects, other invertebrates, and vertebrates. Sir William Flower will undertake the principal duties of Keeper of the Department, in addition to those of Director of the Natural History division of the Museum. A junior assistant will be appointed by competition, so as to keep up the numerical strength of the staff of the department. He will probably be attached to the entomological section, which although already the largest, still requires strengthening in order to cope with the arrangement of the vast number of specimens continually being added to the collection.

WE notice the announcement that, on November 20, Mr. Balfour will receive a deputation from the Association of Chambers of Commerce, in reference to the adoption of the metric system. Our readers will remember that this subject has been considered by a Select Committee of the House of Commons, which has recommended that the metric system of weights and measures be at once legalised for all purposes, and, after a lapse of two years, be rendered compulsory by Act of Parliament. The deputation will present to the First Lord of the Treasury memorials which have been prepared by the Association and by the Leeds and other Chambers of Commerce, urging the Government to bring in a Bill next Session for the purpose of carrying out these recommendations. We trust that the need for the reform of our present cumbersome system will be forcibly impressed upon the Government.

A STRONG American Committee is being formed to act with the Huxley Memorial Committee. *Science* states that substantially all the American scientific men who have been thought of as possibly willing to serve have, so far as approached, signified their willingness to do what they can in the matter. The biologists are likely to be well represented, particularly, and the leaders in scientific work in every field will do their full share. It is hoped and anticipated by our contemporary that the contributions from the United States will rival those of Great Britain, and exceed those of any other nation.

THE suggestion put forward by us, a fortnight ago, that the London County Council, or some other public body, should reciprocate the erection of a statue to Newton by the Paris Municipality, has not passed unnoticed in France. We indicated either Laplace or Lavoisier as a suitable subject for a statue in London; but the *Petit Journal*, in commending the idea, suggests that the right person to be honoured is Voltaire, who was an exile in England from 1726 to 1729, and who returned to France a great admirer of Newton. Voltaire was an enthusiastic exponent of Newtonian principles, and it was largely due to his support of them, in scientific and popular writings, that Descartes' vortex theory was rejected by the Paris Academy of Sciences.

The second International Congress of Applied Chemistry will be held in Paris next year. The Congress will be organised in ten sections, under the following heads: (1) Sugar and sugar-refinery; (2) Industries concerned with fermentation; (3) Agricultural industries; (4) Agricultural chemistry; (5) Official and commercial analyses of substances liable to duty; (6) Industrial chemistry; (7) Photography; (8) Metallurgy, mining, and explosives; (9) Biology, medical, pharmaceutical, and hygienic analysis; (10) Electro-chemistry. An International Exhibition of Chemical and Agricultural Industries will be held during the Congress, and for that purpose the Government has given the use of the whole of the Palais de l'Industrie.

A SIGN of advance in Africa comes to us in the shape of an announcement of the establishment of a monthly journal of South African science, arts, and crafts. The *Scientific African* (for that is the name of the new periodical) will contain popular scientific articles, written by experts, on South African animals, plants, rocks, and minerals, and giving information as to the habits, uses, and occurrences of organic and inorganic matter in South Africa and elsewhere. All the industries of South Africa, in the Colony, Transvaal, Free State, Rhodesia, &c., will be described, with photographic illustrations of the interiors of factories, the workings of mines and collieries, bridges,

harbour works, special processes in agriculture, and other industries by which the wealth and comfort of South Africa is being enhanced. It is intended to give the latest scientific news, and the columns of the paper will be open to the discussion of scientific matters. The *Scientific African* may thus do good service in collecting and publishing observations on the natural history of Africa, and we extend to it a hearty welcome.

THE death is announced of Dr. P. Bertkau, Professor of Zoology in the University of Bonn; and of Dr. Gustav Wilhelm, Professor of Agriculture in the Technische Hochschule of Gratz.

AT the commencement of this month, a Laboratoire d'Études et de Recherches, connected with the École de Physique et de Chemie industrelles, was opened at Paris. By paying a nominal monthly sum to the Paris Municipal Council, any one desiring to work in the laboratory will have placed at his disposal the materials required for his experiments. On the face of it, this seems an ideal means of furthering scientific research.

THE opening meeting of the new session of the Institution of Civil Engineers was held on Tuesday, in the new premises of the Institution, and Sir Benjamin Baker delivered his presidential address. The Emperor of Germany was elected an honorary member at the same meeting. This brings the number of honorary members up to twenty, out of a total membership of 6730.

A BRILLIANT display of aurora was observed in many parts of the British Islands on Saturday night, the 9th inst., following an exceptionally fine day during the recent unsettled and rainy period. But this temporary improvement was succeeded on Sunday by a barometrical disturbance of considerable intensity which reached our western coasts from the Atlantic, causing strong gales over the kingdom generally, and accompanied with heavy rainfall in the northern and western districts. The barometer fell as low as 28·05 inches in the Hebrides, and the changes of pressure generally were very considerable. The gale was characterised by heavy gusts, and these were at times very violent in the south and west; at Greenwich Observatory, a pressure of 19 lbs. on the square foot was recorded at midnight on the 10th.

THE Quarterly Summary of the *Weekly Weather Report* for July to September last, furnishes valuable means for the comparison of temperature, rainfall, &c., for the summer quarter of the last thirty years, in the principal wheat-producing and grazing districts of the British Islands. The tables show that the highest mean temperature for the three months was 61°·7 in the south of England, and the lowest 55°·4 in the north of Scotland; the mean excess over the whole of the country was 1°. During the last thirty years, the greatest mean excess was 2°·8 in the year 1868, and the greatest deficiency 2°·5 in 1888; there have only been four years with an excess of temperature since 1881. The mean rainfall for the whole of the British Islands during the quarter was 9·1 inches, being a deficiency of 0·3 inch on the average of thirty years. The average fall during this long period was largest in the west of Scotland, 11·8 inches, and lowest in the east of England, 7·5 inches.

THE third International Congress of Psychology will be held at Munich, August 4-7, 1896. The International Committee of Organisation is constituted as follows:—President, Prof. Dr. Stumpf; vice-president, Prof. Dr. Lipps; general secretary, Dr. Frhr. von Schrenck-Notzing; and twenty-five members, including, as representatives of British Psychology, Prof. Bain, Prof. Ferrier, Mr. F. W. H. Myers, Prof. Schäfer, Prof. Sidgwick, Prof. Sully, and Dr. Ward. The Congress will be opened on the morning of August 4, 1896, in the great "Aula" of the Royal University. All who desire to further the progress of psychology, and to foster personal relations among the students of psychology in different nations, are invited to take part in the meetings. The following is the provisional programme of work:—Section I. Psychophysiology. (*a*) Anatomy and Physiology of the brain and of the sense-organs (somatic basis of psychical life). Development of nerve-centres; theory of localisation and of neurons, paths of association and structure of the brain. Psychica functions of the central parts; reflexes, automatism, innervation, specific energies. (*b*) Psychophysics. Connection between physical and psychical processes; psychophysical methods; the law of Fechner. Physiology of the senses (muscular and cutaneous sensibility, audition, light-perception, audition colorée); psychical effects of certain agents (medicines). Reaction times. Measurement of vegetative reactions (inspiration, pulse, muscle-fatigue). Section II. Psychology of the normal individual. Scope, methods, and resources of Psychology. Observation and experiment: Psychology of sensations: Sensation and idea, memory and reproduction: Laws of association, fusion of ideas: Consciousness and unconsciousness, attention, habit, expectation, exercise: Perception of space (by sight, by touch, by the other senses); consciousness of depth-dimension, optical illusions. Perception of time. Theory of knowledge. Imagination. Theory of feeling. Feeling and sensation. Sensuous, æsthetic, ethical and logical feeling. Emotions. Laws of feeling: Theory of will. Feeling of willing and voluntary action. Expressive movements. Facts of ethics: Self-consciousness. Development of personality. Individual differences. Hypnotism, theory of suggestion, normal sleep, dreams: Psychical automatism: Suggestion in relation to pædagogics and criminality; pædagogical psychology. Section III. Psychopathology. Heredity in Psychopathology: Statistics: Can acquired qualities be transferred by inheritance? Psychical relations (somatic and psychic heredity), phenomena of degeneration, psychopathic inferiority (insane temperament): Genius and degeneration; moral and social importance of heredity Psychology in relation to criminality and jurisprudence. Functional nerve-disease (hysteria and epilepsy). Alternating consciousness; psychical infection; the pathological side of hypnotism; pathological states of sleep. Psychotherapy and suggestive treatment. Cognate phenomena; mental suggestion, telepathy, transposition of senses; international statistics of hallucinations. Hallucinations and illusions; imperative ideas, aphasia and similar pathological phenomena. Section IV. Comparative Psychology. Moral-statistics. The psychical life of the child. The psychical functions of animals. Ethnographical and anthropological psychology. Comparative psychology of languages; graphology. Forms of application may be obtained from the General Secretary, or from Prof. Sully, East Heath Road, Hampstead, N.W.

THE new quarterly number of the *Journal of the Royal Agricultural Society* (third series, No. 23) is largely occupied with reports of the Society's country meeting, held this year at Darlington. Among the novelties exhibited was a milking machine capable of milking ten cows simultaneously in about twelve minutes. The ingenious part of the apparatus appears to be the teat-cups, which are made of india-rubber of varying thickness, so as to reproduce as nearly as possible the kind of pressure exerted in the operation of hand-milking; a small steam-engine and a vacuum pump are the adjuncts. Papers of scientific interest include one by Prof. Brown, late Director of the Veterinary Department, on "Sheep-Scab in its Relation to Sheep Husbandry," in which the acari of scab are described and illustrated. Sir John Thorold explains the value, as food for calves, of the meat meal which is a by-product in the making of essence of beef. Mr. C. G. Roberts advocates the modification of threshing machines in such a way as to deal with the ears only, thereby avoiding the great waste of power which has been proved to occur when the entire straw is driven—and use-

lessly driven—through the machine. Dr. E. J. McWeeney contributes an illustrated paper on *Phoma Betæ* (Frank), a fungus that injures mangel. A lengthy paper on village water supplies deals with a subject of increasing importance in rural districts. In the statistical section of the journal it is stated that the wheat crop in Great Britain has this year suffered an unprecedented diminution to the extent of over half a million acres, or 26·5 per cent., and a table is given to show that the wheat area diminished in every county in England, without exception, the greatest decrease being one of 40,890 acres in Lincolnshire.

The papillary ridges on the hands and feet of monkeys and men form the subject of a paper received from Dr. D. Hepburn, and communicated by him to the Royal Dublin Society, from the *Transactions* of which (vol. v. series ii., 1895) it has been taken. Galton has shown that the great variety in the designs of the patterns among human finger-prints admit of classification under a small number of primary forms. It seemed probable, therefore, that among monkeys the primary forms of the patterns of human finger-prints might be found in conditions sufficiently simple to afford a key to the production of the more elaborate human patterns. With the idea of throwing light upon this point, Dr. Hepburn has prepared and examined a considerable number of impressions from the hands and feet of living Primates. In the chimpanzee and orang-utan, patterns were found similar to those commonly seen in man, whereas among lower monkeys the patterns approximated more closely to those found in the palm or sole. The conclusions arrived at are as follows: (1) The papillary ridges and their intervening furrows are adjuncts to the prehensile function and power of the hands and feet *as well as* arrangements associated with increased sensibility and discrimination of the sense of touch. (2) The eminences on which papillary ridges form designs or patterns are specially developed areas raised above the general level of surrounding parts. They are also special developments in relation to the prehensile function. This accounts for their constancy in the hands and feet of animals which have these organs modified for prehension. (3) The "design" which covers each of these eminences has its character determined by the position, shape, and dimensions of the particular eminence.

An improved calorimeter, for the application of the method of mixtures in determining specific heats, is described by Mr. F. A. Waterman in the current number of the *Philosophical Magazine*. Mr. Hesehus's ingenious suggestion is acted upon, to maintain the calorimeter, after the introduction of the heated body, at a constant temperature by means of cold water, instead of measuring the rise of temperature of the calorimeter. This arrangement gets rid of the radiation error, and eliminates the "water equivalent" of the vessel. By dropping the cold water in, stirring is also made unnecessary. The method has been placed by Mr. Waterman upon a footing of equality at least with other methods, but his success may be partly due to other improvements. The body experimented upon is heated by a coil of wire conveying a current, and surrounded by ice. The initial temperature of the body may thus be regulated by simply maintaining the current at a certain strength, and this temperature can be kept constant for five or six hours together to within 0°·1 C. The body is then plunged into a silver calorimeter surrounded by the bulb of a delicate air thermometer indicating a difference of temperature of 0°·01 C. The cold water is contained in a copper vessel having the shape of an inverted cone surrounded by ice. In this manner the ice cannot melt away and leave a free space round the vessel. The water-dropping arrangement and the electric heater are mounted on vertical axes in such a manner that they can be quickly swung into position just over the calorimeter. After the heated solid or liquid has been dropped in, the water-dropper is set to work, at first rapidly, and then slowly until the body has assumed the original temperature of the calorimeter. For bodies of the same weight and the same initial temperature, the specific heat is then simply measured by the amount of ice-cold water necessary to cool them to the temperature of the room.

A very useful summary of the results so far obtained by the new treatment of diphtheria with antitoxin has just been issued in pamphlet form by Dr. Welch, Professor of Pathology in the Johns Hopkins University, Baltimore. It is reprinted from the *Transactions* of the Association of American Physicians, and is an expansion of an address recently delivered by the author before the Association. Statistics have been carefully collected from all parts of the world, and the reduction in the case mortality for diphtheria by serum treatment is brought out in a very striking manner. Perhaps the best testimonial to the efficacy of the new treatment is furnished by the experience of Baginsky and others, who record the results obtained during an involuntary pause in the serum treatment caused by failure in the supply of serum. Thus Baginsky states that between March 1894 and March 1895, 525 children were treated with antitoxin with a fatality of 15·6 per cent. During the period when the supply of serum was exhausted, 126 children were treated without antitoxin with a fatality of 48·4 per cent. Similarly, Körte noted a rise in fatality from 33·1 per cent. during the serum period to 53·8 when no serum was procurable, and during an epidemic of diphtheria at Trieste the fatality rose from 18·7 per cent. to 50 per cent. when the supply of serum failed. The *Deutsche medicinische Wochenschrift* has instituted a collective investigation of all the cases of diphtheria treated with serum, and the second provisional report was published last August. Such statistics should prove of inestimable value in assisting the formation of a correct official judgment of the therapeutic value of the antitoxin; meanwhile, Dr. Welch states that "the study so far of the results of the treatment of over seven thousand cases of diphtheria by antitoxin demonstrates beyond all reasonable doubt that anti-diphtheritic serum is a specific curative agent for diphtheria surpassing in its efficacy all other known methods of treatment for this disease," whilst "the essential harmlessness of the serum has been demonstrated by over a hundred thousand injections."

The second part of the new ethnological journal, *Ethnoligsches Notizblatt*, has just appeared. Amongst other articles may be noted a short paper on two old carved canoe prows from New Zealand, by Dr. von Luschan, illustrated by a photographic plate. Prof. Grünwedel writes on representations of Gautama from Upper Birmah and other Indian notes. Dr. F. W. K. Müller describes a Japanese picture of the World-Mountain Meru. Some antique clay tablets from Guatemala are described and illustrated by Dr. E. Seler. Prof. W. Grube gives a list of the Chinese gods of the lower classes in Amoy. Some of the specimens collected by Count von Götzen, during his rapid journey across Africa, are described by Dr. Weule; the Count gave the whole of his valuable collection to the Berlin Museum. Under the title of "Anthropological Anniversary" in reference to the twenty-fifth anniversary of the Berlin Anthropological Society, Prof. Bastian gives an eminently characteristic review of anthropological research from his own point of view; he also has a notice on three quipus collected by Dr. Uhle: these are figured. The last half of the journal is occupied with notes and reviews of recent anthropological literature, most of which are signed, and to which Prof. Bastian largely contributes. While dealing with ethnographical matters in a way common to other similar journals, the editorial committee is evidently paying special attention to the philosophical aspects of anthropology, apparently under the guidance

of Prof. A. Bastian, and thus the journal will appeal to a wider circle of readers, and tend to advance ethnological studies.

VOL. III. No. 4 of *Contributions from the U.S. National Herbarium* consists of a "Flora of the Sand-hills of Nebraska," by Mr. P. A. Rydberg. The district consists almost entirely of sand-hills formed by the action of the wind, and still constantly altering their configuration from the same cause. The production of soil is only rendered possible by the holding together of the sand by the roots of grasses.

DR. GEORGE KING, F.R.S., Director of the Botanical Survey of India, has forwarded his report for the year 1894-95. Much work has been done during the year in the botanical survey of Northern India by Mr. J. F. Duthie. Mr. G. M. Woodrow has discovered that the tree from which the "date" matting so common in Poona is made, is *Phœnix robusta*, Hook. f.

WE have received, from Messrs. Baillière, Tindall, and Cox, a slender volume, in which is described the Tallerman-Sheffield Hot-Air Bath, with notes on its use in various hospitals. The invention is for the treatment of rheumatism, gout, rheumatic arthritis and similar complaints, by the local application of superheated dry air.

A PAMPHLET entitled "Clouds and Weather," written by Capt. D. Wilson-Barker, and illustrated from twenty-four photographs of clouds taken by him, has just been published at the office of the *Shipping World*. The pamphlet has been prepared for navigators, and is intended to show the interdependence of cloud and weather, so that "they who go down to the sea in ships" may know what relations between the two appear generally to hold good.

AMONG Mr. Murray's announcements of forthcoming works is one entitled "The Great Rift Valley: an Account of a Journey to Mount Kenya and Lake Baringo," by Dr. J. W. Gregory. It will contain a narrative of the journey, and chapters giving some account of the geology and ethnography of the eastern half of British East Africa, and notes on its flora and fauna. One chapter discusses "The Problems of the Distribution of the East African Flora and Fauna." The work will be illustrated by numerous maps and illustrations.

THE current number of the *Journal* of the Chemical Society contains an inset with reference to the Collective Index of the Transactions, Abstracts, and Proceedings, which the Society has determined to publish. The Index will be in two volumes, vol. i. extending from 1873 to 1882, and vol. ii. from 1883 to 1892. Both volumes will be sent to those who have been members of the Society since the end of 1882. Vol. ii. will be sent to Fellows who have joined the Society between January 1, 1883, and December 31, 1892. Fellows who are ineligible to receive gratis copies, and those who neglect to apply for them before the end of this year (or March 1, 1896, for Fellows resident abroad), may obtain them by purchase.

THE ninth edition of Müller-Pouillet's "Lehrbuch der Physik und Meteorologie," enlarged and revised by Dr. L. Pfaundler and Dr. Otto Lummer, is being published in parts by Herren Friedrich Vieweg und Sohn, Brunswick. We have previously announced the publication of several sections of this elaborate work (which, as a whole, makes three volumes, illustrated by no less than two thousand figures), and now notice the issue of the part of the second volume dealing with spectrum analysis, polarisation, double refraction, and the wave-theory of light. The complete second volume will take in both light and heat, but the optical section is itself divided into two parts, published separately, and it is the second of these parts that has just appeared. The treatment of the subject is full, and the value of the text is increased to the student by copious references to optical memoirs, papers, and reports.

WE have on our table several recently-published volumes referring to the proceedings of different learned societies, but limits of space prevent us from giving more than a passing mention of a few of the papers in them. In vol. xxviii. of the *Proceedings* of the Royal Society of New South Wales, Prof. Anderson Stuart's presidential address, and the communications to the Society in the latter half of last year, are printed. Among the papers we notice: "From Number to Quaternion," in which M. G. Fleuri shows how mathematicians may pass quite naturally from the idea of number to that of quaternion; an account of an aboriginal Bora held at Gundabloui in 1894, by Mr. R. H. Mathews; Mr. H. A. Hunt's essay on "Southerly Bursters," which gained the Abercromby prize of £25; the timbers of New South Wales, by Mr. J. V. de Coque; note on Australasian and other stone implements, by Prof. A. Liversidge; and an account of the distribution and collection of current-papers sent adrift to indicate the direction of the coastal currents around Australia, Tasmania, and New Zealand, by Mr. H. C. Russell. The volume contains forty-six plates illustrating the papers in it.

IN the *Mitteilungen* of the Berne Naturforschenden Gesellschaft for 1894 (Nos. 1335-1372), edited by Prof. J. H. Graf, Dr. J. G. Glur has a long paper on the fauna of lake-dwellings; Prof. G. Huber describes shooting-stars and meteorites, and the part these celestial bodies play in the universe, his paper being a good historical account of what is known about them; Dr. F. Stähli discusses the foci of cylinders; Dr. E. Baumberger gives a contribution to the geology of the Bieler Lake; and Dr. C. Wagner gives an analysis of Bessel's function of the first order. The volume containing these papers was received through Messrs. Williams and Norgate, who sent at the same time the *Compte rendu* of the seventy-seventh meeting of the Société Helvétique des Sciences Naturelles, held at Schaffhouse last year, and the *Verhandlungen* containing the reports of committees, and obituary notices of the late Dr. Rudolf Wolf, de Marignac (whose portrait forms a frontispiece), Louis de Coulon and B. Schenk.

THE November number of *Science Progress* contains several very good articles. Prof. W. Stirling contributes to it a detailed account of the life, personality, and work of the great physiologist and teacher, Carl Ludwig, and Dr. Sims Woodhead give a similar notice of Pasteur. Mr. F. H. Neville writes on the chemical nature of alloys and Dr. John Beddoe, F.R.S., on anthropometric research in India, his paper chiefly referring to the investigations made by Mr. H. H. Risley, with Governmental authority and support, into the anthropometry of the Bengal Presidency. One of the inferences which Mr. Risley drew from his investigation was that the castes in India are really ethnological, and not merely social divisions. Referring to a comparison of the size of head in the several provinces, Dr. Beddoe remarks: "Here the brachykephals surpass the dolichos, the Aryans the aborigines, the upper surpass the lower castes. But the Brahmans, despite their claims to be considered a kind of intellectual aristocracy, do not seem to surpass other high-caste men, unless it be in the dimensions of the forehead; and the Kaysaths, or writers, almost all of whom live by their brains and their pens, do not stand very much above the average. The differences are not inconsiderable; they exceed probably those which obtain between the superior and inferior classes in our own country; but I do not think they yield any evidence in support of the inheritance of acquired characters." Other papers in our contemporary are: "The Present State of Floral Biology," by Mr. J. C. Willis, and "Present Knowledge of the Mechanical Testing of Iron and Steel," by Prof. Hudson Beare.

THE additions to the Zoological Society's Gardens during the past week include a Western Slender-billed Cockatoo (*Licmetis pasinator*) from Western Australia, presented by Mrs. Halford Stephens; a Crossed Snake (*Psammophis crucifer*), a Hoary Snake (*Coronella cana*), two Ring-hals Snakes (*Sepedon hæmachtes*) from South Africa, presented by Mr. J. E. Matcham; a Common Wombat (*Phascolomys wombat*), a White-backed Piping Crow (*Gymnorhin leuconota*) from Australia, deposited; wo Pennant's Parrakeets (*Platycercus pennanti*) from Australia, purchased; a Rufous Rat Kangaroo (*Hypsiprymnus rufescens*), a Red Kangaroo (*Macropus rufus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE TEMPERATURE OF THE SUN.—Ebert's recent estimate of the solar temperature (NATURE, vol. lii. p. 232), based upon Langley's energy curves for heated solid bodies, is called in question by Dr. Paschen (*Astrophysical Journal*, vol. ii. p. 202). It appears that certain precautions have not been taken in formulating the law derived from experimental data, and that consequently the law does not hold even for the limits of temperature between which direct observations can be made. The chief defects of the former evaluations is that the prismatic energy curves have not been transformed into those for the normal spectrum; and when this is taken into account, the supposition that the wave-length of maximum energy is inversely proportional to the square root of the absolute temperature falls to the ground.

From a series of experiments made with the object of furthering theoretical investigations, Dr. Paschen considers it extremely probable that "the wave-length of the maximum of energy in the spectrum of an absolutely black body is inversely proportional to the absolute temperature." Assuming provisionally as the quantitative results of his observations, wave-length of max. energy × absolute temp. = 2700, and adopting Langley's value of $0\mu\cdot 5$ (μ = ·001 mm.) for the position of maximum energy in the normal solar spectrum, Dr. Paschen finds the solar temperature to be 5400° on the absolute scale, or 5130° C. This means that the sun gives an energy spectrum which is the same as that of an absolutely black body at 5130° C.; and this would be its temperature if its light were entirely a consequence of its heated condition, and if its surface possessed no selective reflection. Attention is drawn to the fact that as our experimental methods are improved, our estimates of the magnitude of the sun's temperature are reduced. Dr. Paschen's value is more than a thousand degrees lower than that of Messrs. Wilson and Gray.

THE DOUBLE STAR OΣ·285.—Dr. See, to whom we are indebted for the revision of the orbits of so many double stars, has lately given us another in the case of OΣ·285 (*Ast. Jour.* No. 356). We are almost tempted to ask whether any practical good results from the premature attempt to determine an orbit where insufficient observations exist, or where the chance errors of observations mask the apparent path of the star. Of course, one very practical value such inquiries may have, especially in the case of a close double star, is to point out the times when observations are likely to prove possible and effective. But the question arises, whether an elaborate interpolation formula or real elliptic elements are dealt with. We are the more concerned to put this question, because Dr. See himself points out that Mr. Gore has, from practically the same observations, given elements strikingly at variance with those to which he has been conducted. The more conspicuous differences between the two sets of elements are shown below.

	Gore (1845-1892).		See (1845-1895).
Period ...	118·57 years	...	76·67 years
Excentricity ...	0·58 ,,	...	0·470 ,,
Node ...	106°·58′ ,,	...	62°·2 ,,
Inclination ...	45·42 ,,	...	41·95 ,,

The difficulty of deciding which of the two orbits is the more probable representation of the motion is increased by the fact, that the position angle computed from both is very similar. Previous to 1865 and subsequent to 1887 (in the interval 1865–87, the observations were very uncertain, owing to the close approach of the components) the position angles computed from the two orbits for the same date are rarely separated by a degree, while occasionally the observations differ from the computed place by as much as ten degrees. Dr. See gives an ephemeris for the next five years, and if trustworthy observations can be made of stars separated by about 0″·3, additional light will be thrown on the motion of this interesting pair.

THE SPECTRUM OF α AQUILÆ.—The fact that the lines in the spectrum of α Aquilæ are much broader than the corresponding lines in the majority of stellar spectra, was first noticed by Prof. Pickering, who suggested that this appearance might be due to a very rapid rotation of the star. Photographs taken at Kensington and Potsdam have also shown this haziness of the lines.

The spectrum of this star has formed the subject of a somewhat extended research by M. Deslandres at the Paris Observatory, and by the use of a comparison spectrum enabling him to determine the velocity in the line of sight, he has obtained results of great interest (*Comptes rendus*, Nov. 4, p. 629). He finds that very frequently there are fine double bright lines running through the middle of the dark lines of hydrogen, and even sometimes through those of iron and calcium; the brightness of these lines varies with respect to the general intensity of the spectrum, and M. Deslandres attributes them to the chromosphere of the star.

Measurements of the radial velocity are given for fifty-six dates, and they clearly indicate periodic but complex variations. The maximum velocity of approach with respect to the sun was 38·4 km. per second on September 19, 1892, and of recession 11·4 km. per second on July 25, 1895. There appears to be a great oscillation with a maximum velocity every forty-three days, and superposed on this are one or more secondary oscillations, one of which has probably a period of about five days. M. Deslandres believes his results to indicate that Altaïr is at least a spectroscopic triple star; but he states that for a more complete knowledge of the phenomena, better apparatus and a less variable sky than that of Paris will be necessary.

β Ursæ Minoris also exhibits rapid fluctuations of velocity, and M. Deslandres' results in connection with this star will form the subject of a future paper.

VARIABILITY OF RED STARS.—In the current number of *Knowledge*, Dr. Brester gives a general account of his theory as to the cause of variability in red stars (see NATURE, vol. xxxix. p. 492), and extends it a step in order to account for the appearance of bright lines. It is assumed that the stars in question are cooling bodies, and that the atmospheres are sufficiently cooled down to permit the existence of chemical compounds. When some of the vapours are cooled to the dew point, they will condense in obscuring clouds, and produce a minimum without any reduction of temperature. In addition to saturated vapours, if we follow Dr. Brester, the atmospheres will also contain molecules of dissociated matter, which will only combine after the condensation of the saturated vapours has rendered the mixture sufficiently concentrated. The combination of the dissociated molecules produces heat enough to vapourise the clouds, and the maximum is restored by the opening to view of the constantly glowing interior. The presence of bright lines in the spectrum of a variable star near maximum is ascribed to "luminescence" produced by the chemical combination of the dissociated molecules. Thus, the bright lines at the maximum, according to Dr. Brester, are not the effect of heat, but rather of cooling. Dr. Brester finds some justification for this supposed origin of bright lines in the fact that carbon bisulphide gives a discontinuous spectrum at no higher a temperature than 150°; but it must be remembered that the bright lines in question are usually those of hydrogen, and there is no experimental demonstration that these lines can be produced except at a high temperature. To us it seems easier to regard the bright lines of hydrogen as being produced by true elevations of temperature about the time of maximum, such as are explained by the meteoritic hypothesis.

TYPHOID FEVER EPIDEMICS IN AMERICA.

THE factors which control the dissemination of disease are so numerous, and in many cases so complicated, that it is often only after long and patient searching that an epidemic is successfully tracked to the original nidus from which it has sprung.

By the careful record of data of this description, compiled with accuracy and care, we shall gradually become possessed of trustworthy material out of which an historical survey may be built up, and the task of deciphering the course and conduct of epidemic diseases materially lightened.

As a contribution to the history of typhoid fever epidemics, we warmly welcome the able report of some outbreaks of this disease in Massachusetts, made by, as well as under the direction of, Prof. W. T. Sedgwick.

The work before us was included, in the first instance, in the Twenty-fourth Annual Report of the State Board of Health of Massachusetts, but has been, and we think wisely, issued also as a separate pamphlet. No less than nine outbreaks of typhoid fever were investigated, but perhaps the most interesting and important is that which occurred in Lowell, one of the largest cities in the Merrimack Valley, and depending mainly for its water supply on the Merrimack River. Public attention was first called in December 1890 to the serious character of the epidemic of typhoid fever in the city, when it became known that in the preceding month 122 cases had been reported, and twenty-eight deaths from this disease had taken place. After a long and exhaustive investigation, the river water supply became suspected of being the vehicle of the specific infection to which the epidemic must be attributed. Prof. Sedgwick set to work, therefore, to find if there had been any special or unusual infection of the river *above* Lowell, and the discovery was made that an outbreak of typhoid fever, "such as had not been known for forty years," had occurred during the previous August, September, and October in a small village only three miles above Lowell, and situated on a small stream running into the Merrimack River. Four at least of the cases of typhoid fever were proved to have directly infected this small brook, which joins the river only two and a half miles above the intake of the Lowell Waterworks. Dr. Sedgwick states in his report that "the Merrimack River is regularly polluted above Lowell, not only by Stony Brook, but very extensively by the large cities of Nashua, Manchester, Concord, and Fitchburg, the sewers of all of which pour their raw contents directly into the Merrimack River or the Nashua. This they had been doing for months and years; and to the fact that Lowell has been willing to drink this regularly polluted water, *totally unpurified by filtration*, is chargeable the fact that typhoid fever has annually been excessive in that city. But the conditions were no worse than usual in these cities in September and October 1890. There was, however, as has been shown, an infection of a small and seemingly insignificant feeder of the Merrimack only two and a half miles above the intake of the Lowell Water Works, such as is not known to have occurred there for forty years." With respect to the chemical and bacterial examinations of the water, Dr. Sedgwick writes as follows:—

"These were made in the hope of discovering some unusual condition of the river, or of possibly detecting the Eberth bacillus itself. But, as usually happens in typhoid fever epidemics, the worst was over before the examinations began. The chemical examinations showed nothing that was not already known. The bacterial analyses revealed a noteworthy excess of *Bacillus coli communis*, confirming the chemical evidence of the presence of sewage in the city water as drawn from the river, but no Eberth bacilli were found."

We do not, however, attach perhaps the same importance as Dr. Sedgwick to the detection of the *B. coli communis* in the water, as we believe that this organism, or forms closely allied to it, may be found far more frequently present in pure peaty or other upland surface waters than is usually surmised, and that such microbial forms are not *necessarily* indicative of the access of sewage to a given water-supply.

The epidemic of typhoid fever, which apparently started above Lowell, infecting the Merrimack River, supplying that city with water, subsequently extended to Lawrence, situated on the same river, nine miles below Lowell, and a so using its waters for drinking purposes. In this connection Dr. Sedgwick remarks: "Inasmuch as there is good reason to believe that this unusual epidemic was caused by the unusual infection of the river at North Chelmsford and at Lowell, it is interesting to observe that some of the infectious material was apparently able to survive the comparatively unfavourable conditions imposed by the long and slow passage through the Lawrence reservoir and the service pipes." [The "unfavourable conditions" here referred to are the processes of sedimentation to which the microbial contents of the water would be exposed under these circumstances.] "It would seem therefore that, while much of it must have perished *en route*, some of it did not; and, as the time of year was November and December, we are safe in concluding that during these months, under certain conditions, some of the infectious material of typhoid fever may be conveyed nine miles by a river, may slowly travel through a distributing reservoir, and still remain effective to a very dangerous extent if swallowed in drinking water." During the four years preceding 1891, the average mortality from typhoid fever in Lowell is stated to have been 8·44 per 10,000, whilst in 1890-91 it rose to 19·54 per 10,000. Thus the average death-rate from typhoid fever is considerably higher than we experience in London, but it sinks into comparative insignificance when we contrast it with the statistics of typhoid fever in Chicago compiled by Dr. O. M. Huff, of that city. In 1891 the deaths directly attributed to typhoid fever in Chicago amounted to no less than 16·64 per 10,000. In 1892 the condition of things was somewhat improved, although the death-rate, says Dr. Huff, still remained three times as great as in New York, five times as great as in London, and more than six times the rate of Berlin. Dr. Huff has made a minute study of the relation of typhoid fever to the water supply of Chicago, and has come to the conclusion that the contamination of the drinking water supplied to the city with sewage is the "efficient cause" of this alarming mortality. It is stated that Lake Michigan "serves both as a water-bucket and a cesspool for Chicago." An American scientific journal, in reviewing this report, reasonably suggests that every resident of Chicago ought to be advised of the fact that there is death in the water-pipe.

It is to be hoped that the attention now being bestowed in America on subjects both directly and indirectly connected with public health will lead to beneficial practical results, and that the distribution of water openly contaminated with sewage in its raw, unfiltered condition for drinking purposes, will be summarily prohibited by law in all countries before such grave consequences have again to be met as attended the distribution in Hamburg of raw, unfiltered river Elbe water for dietetic purposes. G. C. Frankland.

AN ACCOUNT OF THE CONSTRUCTION AND STANDARDISATION OF APPARATUS, RECENTLY ACQUIRED BY KEW OBSERVATORY, FOR THE MEASUREMENT OF TEMPERATURE.

The accuracy of the measurements made at Kew Observatory may, without exaggeration, be regarded as a matter of national concern. It is right, therefore, that the scientific public should be made acquainted with the principles involved and the methods of comparison employed in any series of measurements conducted at the Observatory; more especially when a new departure is made, either in the apparatus used or in the nature of the observations.

In the absence from England of Prof. Callendar, F.R.S., the writer, at the request of the Kew Committee, undertook the responsibilities connected with the preparation and standardisation of the apparatus, recently installed at Kew, for the accurate measurement of temperatures—particularly of high temperatures.

It would be impossible, without unduly trespassing upon these pages, to give a full description of the principles on which the measurements of temperatures by platinum thermometers are founded, or of the methods of standardisation adopted. I will, however, endeavour to briefly indicate reasons for our faith in the principles involved and the accuracy of the methods employed.

I make this communication with the (unofficial) consent of the Kew Sub-Committee, to whom the oversight of this matter was delegated; at the same time it should be understood that the writer alone is responsible for the statements, or opinions, advanced in the following pages.

Sir Douglas Galton in his address at Ipswich remarked that "British students of science are compelled to resort to Berlin or Paris when they require to compare their more delicate instruments and apparatus with recognised standards." We may now hope, however, that, at all events as regards temperature measurements, his statement will ere long require modification.

I. *Brief Explanation of the Terminology and of the Principles involved in the Measurements of Temperature by Platinum Thermometers.*

A platinum temperature scale is one so constructed that a rise of one degree on that scale at any temperature would cause the electrical resistance of a platinum wire to increase by one-

hundredth of the difference between its resistance at 100° and 0° C.

Hence, if R be the resistance at any temperature, R_1 the resistance at 100° C., R_0 at 0° C., and *pt* the temperature on the platinum scale, then

$$pt = \frac{R - R_0}{R_1 - R_0} \times 100.$$

The investigations of Prof. Callendar[1] established the relation between *pt* and *t* (where *t* is the temperature on the air scale) over the range 0° to about 600° C. for a particular sample of platinum wire.

This relation is given by the following equation.

$$d = t - pt = \delta\left\{\left(\frac{t}{100}\right)^2 - \frac{t}{100}\right\}. \quad . \quad . \quad . \text{ Eq. } (d)$$

the value of δ for Callendar's wire being 1·57.

If it was at all times possible to obtain platinum wires of *exactly* the same degree of purity as Callendar's, we could at once establish a standard platinum scale, which could be used for purposes of reference independently of any assumptions as to its relation to the air scale. The impossibility of securing uniformity in this respect, however, would, at first sight, appear to be an insuperable impediment to the adoption of such a proposal.

Subsequent experiments by Callendar and myself led, however, to the following conclusion.[2]

That, although the value of δ varies greatly according to the purity of the sample of platinum, the relation given by the equation (*d*) holds true, provided the percentage of impurities is small (this condition is sufficiently fulfilled by ordinary commercial samples).

This conclusion is an exceedingly important one, for (the $t - pt$ curve in every case being a parabola) it is only necessary to determine the resistance at three different temperatures in order to ascertain the appropriate value of δ, and thus to completely standardise the thermometer.

Much experimental work had to be accomplished before we could venture to regard the above proposition as established; but I think that any impartial reader, who cares to study the original papers[3] dealing with this matter, will admit that the evidence is sufficient.

The three temperatures selected for the purposes of standardisation were the melting-point of ice, steam at a pressure of 760 m.m., and the vapour of sulphur at the same pressure.

Certain discrepancies between thermometers thus standardised and others standardised by direct comparison with the air thermometer, led to a redetermination (by means of an air thermometer) of the boiling-point of sulphur, when we found that Regnault's value (448°·34) was too high, our experiments leading to the conclusion that 444°·53 was the correct value.[4]

Subsequent investigations by different observers have confirmed the accuracy of the above conclusions, which may now be regarded as experimentally established over the range 0° to 600° C.

There is, however, a large amount of indirect evidence which indicates that formula (*d*) holds true over a far more extended range.

For example, the results obtained by Messrs. Heycock and Neville (*Chem. Soc. Trans.*, 1895) are entirely dependent on the validity of the above conclusions. They find the freezing-point of copper as 1080°·5 C., whereas Holborn and Wien, using a platinum rhodium couple standardised by direct comparison with the porcelain air thermometer, find 1082° as the value of the same constant.[1]

As illustrating the identity of the results obtained by the use of thermometers having a very different value of δ, I quote the following numbers from Table XII. of Heycock and Neville's paper:—

Pyrometer.	Value of δ.	Freezing-point of gold. °
13	1·500	1061·9
15	2·040	1061·2
18	1·574	1061·4
13A	1·553	1061·9
14	1·511	1062·0

Results of this kind prove that even if the reduction does not express the temperature accurately in the air scale, it at all events gives us a *constant* scale in which all high temperatures can be expressed, and it is further evident that this constant scale differs but little (even at these high temperatures) from the true air scale.[2]

Indications are not wanting that the same relations hold true at very low temperatures.[3]

Finally, a very careful comparison of the platinum and air thermometers over the range 0° to 100° C., and also of the platinum thermometer with the nitrogen standard of the Bureau International, establishes the validity of the methods of observation and reduction at ordinary temperatures.

As regards the constancy of platinum thermometers there should now be little uncertainty. The prevailing doubt (amongst those who have not used them) may be traced to the adverse report of a British Association Committee in 1874, on another form of the instrument, and I would refer those who may be influenced by that report to a letter by Prof. Carey Foster, F.R.S., in NATURE, August 23, 1894.

An inspection of the voluminous tables given in Heycock and Neville's paper (*supra*) will show, however, that when the thermometers are repeatedly exposed to temperatures above 900° or so, a slight permanent increase in FI (the Fundamental Interval = $R_1 - R_0$) is observable. It is probable that this change is due to a permanent thickening of the mica plates by which the wire is supported, and thus, on cooling, the wire is slightly strained. The change is small, and can always be traced by repeating the determinations of R_1 and R_0, and does not appear to appreciably affect the values of δ.

To show the order of magnitude of the change, I give the following illustration, compiled from Table VIII. of Heycock and Neville's paper.

History of Pyrometer 13.

On August 3, 1894, the fundamental interval was 100·64. During the next few months this pyrometer was used for the determination of the freezing-points of the following substances:—

Substance.	Number of determinations.
Silver	10
Aluminium	12
Potassium sulphate	5
Sodium sulphate	4
Sodium carbonate	3
Magnesium	5
Antimony	2
Tin	3
B.P. of sulphur	6

Also the pyrometer had been raised to a bright red heat in a muffle furnace some scores of times, and the exterior porcelain

1 *Phil. Trans. Roy. Soc.* A, 1887.

2 A summary of these experiments is given in *Science Progress*, September 1894.

3 Callendar, *Phil. Trans. Roy. Soc.* A, 1887; Griffiths, "Report of Electrical Standards Committee, B.A. 1890; Heycock and Neville, *Chem. Soc. Journ.* 1890; Griffiths, *Phil. Trans. Roy. Soc.* A, 1891; Callendar and Griffiths, *Phil. Trans. Roy. Soc.* A, 1891; Callendar, *Phil. Mag.*, July 1891; Griffiths and Clark, *Phil. Mag.*, December 1892; Griffiths, *Phil. Trans. Roy. Soc.* A, 1893; *ibid.*, *Proc. Roy. Soc.* vol. lv. 1894; *ibid.*, *Science Progress*, 1894; Thorpe, "Dictionary of Applied Chemistry," article "Thermometry"; Heycock and Neville, *Trans. Chem. Soc.* 1895.

4 In the last edition of Watts's "Dictionary of Chemistry," article "Sulphur," I find that some doubts are expressed (by Mr Pattison Muir) as to the validity of this determination, owing to uncertainty as to the purity of our sample of sulphur. I sub-equently investigated the boiling-point of a specially pure sample by means of one of the platinum thermometers (thermometer E) used during the original comparison of the air and platinum thermometers in sulphur vapour, and I found no evidence of any difference in the boiling-point of the two samples. We may assume, therefore, that if any impurities were present, they were not of such a nature as to influence the temperature of the vapour.

1 The following example illustrates the importance of the alteration in the boiling-point of sulphur. In Table VI. of Heycock and Neville's paper (*supra*) are given the details of an observation on the freezing-point of Cu determined by pyrometer No. 8. They are as follows: $pt_s = 421·29$, $\delta = 1·517$, $d = 159·3$, $t = 1080·7$. If we assumed the validity of Regnault's boiling-point of sulphur (448°·34), the above value of pt_s would change the value of δ to 1·729; this would give $d = 181·6$; hence $t = 1103°·0$. In this case the discrepancy between the results of Holborn and Wien, and Heycock and Neville would be very marked—a difference of 21°·0 as against the present difference of 1°·3.

2 Messrs. Heycock and Neville, in Table XVI. (*Chem. Soc. Trans.*, 1895, p. 195), give Violle's value for the freezing-point of gold as 1035° C., and the discrepancy between this number and that found by them (1061°·7) is consid rable. A redetermination, however, by Violle in 1892 (*Comptes rendus*, 92, p. 866) raised his number to 1045°. Some recent experiments by Le Chatelier (*Comptes rendus*, August 12, 1895) lead that observer to the conclusion that Violle's later value should be further raised by about 15° (or at all events by a number "not exceeding 20°"), *i.e.* to about 1060° C., a very close approximation to the 1061°·7 found by Heycock and Neville in December 1894.

3 Griffiths and Clark, *Phil. Mag.*, December 1892.

tube had on three occasions been removed and replaced by a new one.

At the close of these operations (December 19, 1894) the value of FI had risen to 101·003, an increase of 0·36 per cent.

It should be remembered that in each determination the substances were raised to 50° or 100° above their freezing-points before the observations were taken; for example, the freezing-point of potassium sulphate is given as 1066° C., but it is certain that when determining this point the pyrometer was previously raised to a temperature considerably exceeding 1100°. A study of the original table will show that the rate of increase in FI diminishes with use.

As this question of constancy is of vital importance, Messrs. Heycock and Neville have given me permission to state that they have used only one pyrometer during a continuous series of high-temperature determinations extending over two months of the past summer. When the account of their work is published, it will be found that although the number of the observations on the freezing-points of alloys exceeds some hundreds, the pyrometer is as efficient now as at the commencement of their work. Its FI on July 28 was 100·148, on August 20, 100·357, and on nearly all the intervening days it had been immersed in molten metal at temperatures between 900° and 1000° for five or six hours at a time. A determination of the freezing-point of copper, made at the close of the above series of experiments, gave a value practically identical with that previously published.

Apart from the slight change in FI, above illustrated, there is abundant evidence that when *completely protected from the action of furnace gases* the platinum wire undergoes no change. Space does not permit the accumulation of further evidence, but full information will be found in the papers already referred to.

II. *Description of the Apparatus.*

The facts dwelt upon in Section I. show that if the methods of platinum thermometry are adopted, the measurement of temperature becomes a question of the measurement of electrical resistance, and there are few physical quantities which can, if due precautions are taken, be measured with greater accuracy than the resistance of a conductor. The Kew apparatus, therefore, may be regarded as designed for the accurate measurement of the resistance of a platinum wire, and some of the contrivances introduced with the object of securing greater accuracy are, I believe, peculiar to this apparatus.

The designs were drawn up by Prof. Callendar and myself, after consultation with Mr. Horace Darwin, and the apparatus was constructed by the Cambridge Scientific Instrument Company, Ltd., under the personal direction of Mr. Pye.

Fig. 1 is a diagrammatic view of the connections.

The coils S_1 and S_2 are of equal resistance (about 5 ohms), Q is a set of resistance coils, A B a bridge-wire, and K a thermo-electric key. When the resistances between C_1 and C_2 and P_1 and P_2 are equal, the bridge is balanced if the resistance at Q is zero, and the contact-maker H is at the mark O near the centre of the bridge-wire. The scale of this wire is so graduated that if the reading to right or left of O be added or subtracted from r (the resistance at Q), the result gives the value of P – C where P is the resistance between P_1 and P_2, and C the resistance between C_1 and C_2.

Now $P = p + C_p$, where p is the platinum coil resistance, and C_p the resistance of the leads to that coil, including the thick platinum wires which run down the thermometer stem. An equal pair of leads run from C_1 C_2 to similar thick platinum wires in the thermometer stem, which are connected together at the lower extremities, but have no contact with the coil.

Thus $r \pm OH = p + C_p - C$; and therefore if $C_p = C$, we get $p = r \pm OH$.

The leads C_p and C are everywhere bound together except in the thermometer stem, where they are parallel and adjacent, being held in position by their mica discs, hence changes in C_p and C caused by changes in temperature do not affect the resulting value of p, and thus the readings are independent of the thermometer stem-temperature—a matter of great importance at high temperatures.[1]

A certain amount of stem immersion is, however, necessary, for the lower extremities of the leads must be heated to the bulb temperature, otherwise they would, by conduction, cool the extremities of the coil; this is an additional reason for forming the leads of platinum, which has a low thermal conductivity.

A preliminary series of experiments led to the conclusion that a certain quality of white marble had superior insulating properties to ebonite—the material generally used for the tops of resistance-boxes. This superiority was partially due to its non-hygroscopic properties; for example, I placed slabs of the best ebonite, black marble, and this white marble in an ice-safe for some time. I then removed them one by one to the warm laboratory, and tested them under similar conditions with a "pressure" of 100 volts. The insulating powers of the ebonite and black marble fell off alarmingly, while the white marble was but little affected.

Some difficulty was experienced by the makers in devising a satisfactory method of attachment between the marble and the many brass connections, &c., but this difficulty was at length overcome. The coil and bridge-wire were constructed from one sample of platinum silver. The coil of a platinum thermometer was replaced by a specimen of the wire (diameter ·008 in.) from which the coils were formed, and which had been subjected to the same process of annealing. Its temperature coefficient was then determined with great care over the range 15° to 25° C. (nitrogen scale), and was found to be ·000260 in terms of the

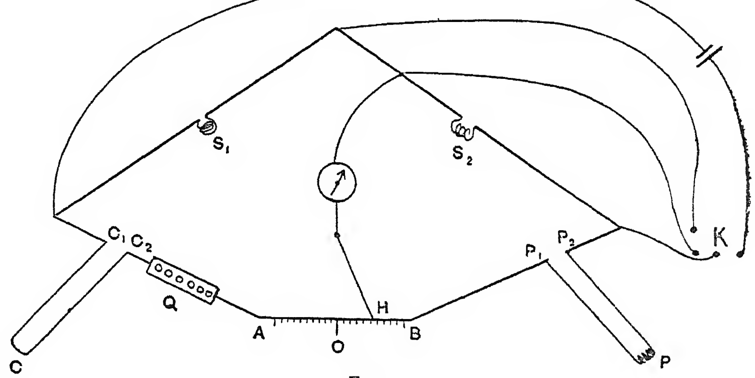

FIG. 1.

resistance at 20° C. I proposed to keep the box when in use at a temperature near 20° C., for it is wise, when feasible, to maintain all measuring instruments at a temperature exceeding that of an ordinary room, for two reasons: (1) it is generally easy to raise the temperature of the apparatus above that of the air, whereas it is extremely difficult to keep it at a lower temperature; (2) when the temperature of the apparatus exceeds that of the room, all its surfaces are kept dry, and also more dust-free than would otherwise be the case.

The greatest difficulty encountered in resistance measurements is (according to my experience) uncertainty as to the actual temperature of the coils. If a resistance-box is placed in a tank, it is true that five sides of it can be maintained at a constant temperature, but the top is necessarily exposed; and since all the coils are ultimately connected with the top, their temperature at times differs considerably from that of the tank.

[1] The *absolute* equality of C and Cp is not essential; both are small as compared with p $\left(\frac{c}{p}\text{ is always less than }\frac{1}{50}\right)$, thus $Cp - C$ is a very small fraction of p, and it is only the temperature change in $Cp - C$ that affects the measurements. The total resistance of the thick copper leads from the box to the thermometer is so small, and they are subject to such comparatively slight changes of temperature, that the temperature change of their difference may almost certainly be neglected. The greater part of Cp and C is the resistance of the platinum stem leads, which are certainly exposed to considerable temperature changes. If, however, they are made of the same platinum as the coil, then any irregularity has nearly the same effect as an alteration in the original length of the coil, and does not appreciably affect the ratio $\frac{R_1}{R_0}$ or the values of pt. In all carefully constructed thermometers the value of $Cp - C$ may be regarded as zero.

Again, the thick coating of paraffin, and the solid core, which are almost universally prevalent, increase the uncertainty, for if any temperature change is taking place the lag is considerable.

These sources of error were diminished as follows: the sides and bottom of the box are the inner walls of a double copper tank, holding about eight gallons of water maintained at a temperature near 20° C. by a regulator. Over the top of the box and tank is fixed a case similar to that of an ordinary balance, the front glass of which is only raised when adjustment of plugs and contact-maker is necessary, all connecting screws being exterior to the case. The silk-covered coils (which are double in all cases to reduce the effects of current heating) are suspended from an ebonite rack within the box. They received

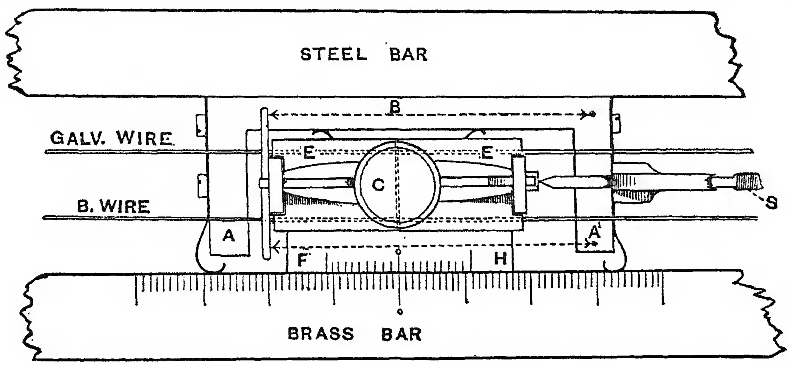

FIG. 2.

the thinnest possible coating of paraffin and are wound loosely and openly, so as to be subjected to no strain, and also to permit free circulation of air to all parts of the wires. An open scale mercury thermometer, with a small bulb, is placed with its bulb contiguous to one of the higher resistance coils. A series of observations leads to the conclusion that, under these circumstances, the thermometer-reading sufficiently indicates the real temperature of the coils, provided of course that no rapid changes are taking place, and this conclusion is borne out by the observations of Messrs. Heycock and Neville on a box similarly protected by a balance case.

The coils were annealed in paraffin at a temperature slightly below that which would carbonise the silk covering.

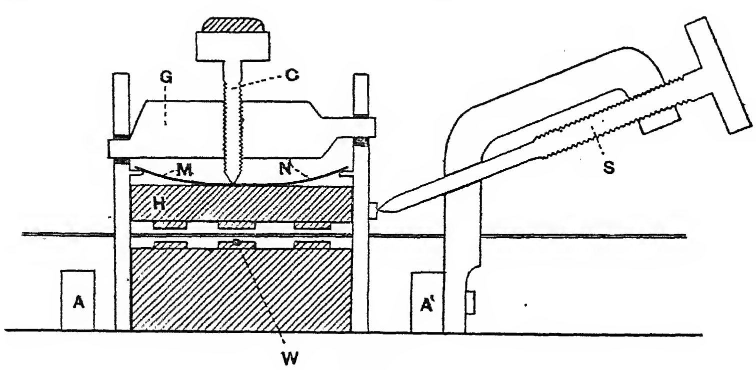

FIG. 3.

The box-unit is (approximately) $\frac{1}{100}$th of a Board of Trade ohm. The coils have the following nominal values in terms of this unit.

A	B	C	D	E	F	G	H	FI
640,	320,	160,	80,	40,	20,	10,	5,	100,

and the bridge-wire has such a section that a change of 1 c.m. in the reading indicates (approximately) a change of 1 unit in *p* (in reality 1 c.m. = ·9957 box units), and the resistance of the thermometers, with one exception, is such that a change of one box unit corresponds to 1° on the platinum scale.

The whole length of the bridge-wire is 30 c.m.; thus any resistance exceeding 40 units can be measured in three or four different ways by changing plugs and bridge-wire contact. Thus the accuracy of the various corrections can at any time be exposed to a severe test.

Great attention was given to the drawing of the bridge-wire, for, although the effect of irregularities would be eliminated by the subsequent calibration, it was desirable to make it as uniform as possible. In this matter the Scientific Instrument Company were very successful, for it was ultimately ascertained that if the wire was assumed as uniform, the greatest resulting error would not exceed 0·005 units.

Before its final attachment to the box, the wire was hung from a conductor, and had a small weight fastened to the lower end, which communicated with a cup of mercury; it was then raised to a bright red heat by means of an electric current, after which the cells were gradually switched off, so that the cooling was slow. The annealing was thus very perfect, and the wire on being released remained quite straight. The coefficient of expansion of this platinum-silver alloy lies between that of steel and brass. A narrow parallelogram was formed, whose longer sides consisted of brass and steel bars respectively—the shorter sides of ebonite. The steel and iron bars were connected at their centres to the marble box top, and the wire placed between, and parallel to, them, its ends being fixed to the ebonite cross-pieces and connected by flexible brass strips to the remainder of the bridge. By this arrangement the tension of the bridge-wire is kept constant when the temperature of the box alters, and, at the same time, the zero-point at the centre remains unchanged in position.

A second platinum-silver wire, permanently connected with the galvanometer, lies alongside the true bridge-wire. The vernier-slide carries a small cross-bar of the same wire placed beneath and at right angles to the bridge and galvanometer wires, and only just clearing them (Fig. 3). When the contact-screw is either forced, or screwed down, both wires are pressed on to the cross-piece by means of pads, and arrangements are made to prevent any pressure being exerted which could injure the bridge-wire. This method has several advantages, one of which is that only similar metals are brought in contact, and thus thermo-electric effects at this junction are avoided.

The vernier reads directly (by means of a microscope) to $\frac{1}{50}$th m.m., thus $\frac{1}{100}$th m.m. can be estimated; *i.e.* approximately 0·001 box units, or 0·00001 ohms.

Great difficulty has hitherto been experienced in constructing a fine adjustment for a bridge-wire contact. It must be of such a nature that it will permit the free movement by hand of the contact-maker to any position. Again, if, owing to an oversight the contact-maker is screwed down, and any of the ordinary means of fine adjustment are used, the bridge-wire is subjected to a scraping action which may affect its section. These difficulties have been overcome by an ingenious device designed for this apparatus by Mr. Horace Darwin.

Fig. 2 is a plan, and Fig. 3 a vertical section of the contact-maker.

A B A' (Fig. 2) is a brass framework which slides between the steel and brass bars previously referred to. An inner block F E E' H stands within the brass framework with a play-space at its ends of about 1 c.m. Springs at A and A' press the brass frame against the steel bar, and springs at E, E' press the inner block against the front brass bar. Thus the pressure of the brass frame against the steel bar is the sum of the pressures of the springs at A, A', E and E', whereas the pressure of the inner block on the front bar at F H is the sum of E and E' only; if, therefore, the screw S is rotated the inner block alone is moved. As the screw S recedes the inner block is made to follow it by means of long springs indicated in the plan by the dotted lines with arrow-heads. If by inadvertence S is turned when the bridge-wire has not been released by the screw C

(Fig. 3), then the outer framework A B A′ moves instead of the inner block.

The arrangement by which the pads in the block H can be either pressed down for temporary, or screwed down for more permanent, observations is shown by the section in Fig. 3. The spring M N lifts the pads off the bridge and galvanometer wires, which therefore do not touch the cross-wire (whose section is shown at W) unless a downward pressure is exerted on the block H.

By holding the head of the screw S the whole contact-maker can be pushed to any desired position.

The vernier is shown at F H (Fig. 2).

The box contains coils of 20 and 100 ohms, which can be thrown into the battery circuit by means of a switch, and also a galvanometer shunt of about $\frac{1}{10}$ the galvanometer resistance.

With the exception of the points to which I have drawn attention, the resistance-box resembles those ordinarily in use.

The galvanometer has a resistance about 5 ohms, and is sensitive and "dead-beat." A fixed scale is placed before the mirror, and the image viewed through a microscope. Very small deflections can thus be observed, and observations can be taken in bright daylight.

This last has a coil whose resistance is 2·5 times as great as he preceding ones.

All these thermometers have been annealed at a temperature of about 1000° C., Nos. 5 and 6 being temporarily placed in porcelain tubes for that purpose.

The apparatus for the standardisation in ice, steam, and sulphur-vapour presents certain distinctive features, most of which, however, are described in *Phil. Trans. Roy. Soc.*, vol. 182 A.

Messrs. Heycock and Neville were so kind as to undertake the design and arrangement of the furnaces, &c., for the high temperature work, which are, in the main, similar to those used during this summer for the purposes of their investigations into the behaviour of alloys. As an account of their work will shortly be published, I shall not venture to anticipate it by any description. Arrangements have been made for (1) the standardisation of thermometers by observations on the freezing-point of silver when placed in a reducing atmosphere;[1] (2) the comparison of the Kew standards with other thermometers over the range 100° to 300° C. by means of a well-stirred bath of a fusible metal covered with paraffin or oil; (3) the comparison over a range 300° to 1200° C. in a bath of melted tin placed in a reducing atmosphere.

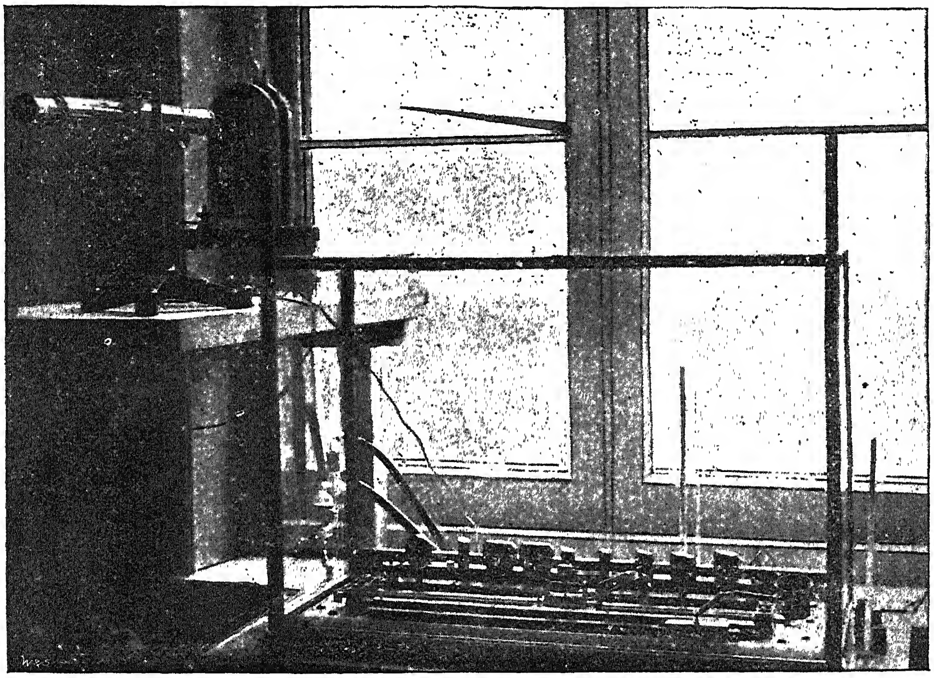

FIG. 4.

Thermo-electric effects (which at high temperatures are occasionally considerable) are eliminated by the use of a special key described in *Phil. Trans. Roy. Soc.*, vol. 184 A, p. 397.

The leads from the box to the thermometer are about five yards in length, and are each composed of 136 strands of copper wire carefully insulated. The thermometers can thus be used in any part of the room.

Six thermometers have been supplied, all of whose coils are formed from the same sample of specially pure platinum wire—diameter 0·006 inches. The length of wire in Nos. 1 to 5 is about 18 inches, the mica framework which supports the coil is from 1¼ to 1½ inches in length, and this portion is termed the bulb.

Nos. 1 and 2 are contained in porcelain tubes 1·2 c.m. in diameter, 40 c.m. long.

Nos. 3 and 4 are contained in porcelain tubes 1·5 c.m. in diameter, 36 c.m. long.

No. 5 is contained in a glass tube 1·4 c.m. in diameter, 40 c.m. long.

No. 6 is contained in a glass tube 1·7 c.m. in diameter, 40 c.m. long.

The whole of the apparatus is placed in a special building erected for this purpose by the Kew Committee, according to designs by Mr. W. N. Shaw, F.R.S., and myself, after consultation with Messrs. Heycock and Neville. The building is found to admirably fulfil its purpose, the only drawback being the defective gas supply, which will, however, shortly be remedied by the insertion of a larger main between the Observatory and the outbuildings.

Fig. 4 (a copy of a photograph by Mr. Hugo) gives the relative positions of box and galvanometer. It will be seen that the observer can manipulate the contact-maker without removing his eye from the galvanometer-microscope, a great advantage when observing small temperature changes. Immediately to the right of the resistance box, but exterior to the limits of this plate, is a large draught-chamber containing the furnaces, &c.

III. *The Standardisation of the Apparatus.*

The necessary operations were as follows:—

No. 1. Determination of the temperature coefficient of coils and bridge-wire.

[1] See letter to NATURE, October 17, 1895.

No. 2. Calibration of bridge-wire and determination of error due to the position of the scale zero mark.

No. 3. Determination of the coil errors.

No. 4. Value of the mean box-unit in terms of the Board of Trade ohm. (This was *not* a necessity for the temperature measurements, but it appeared advisable to ascertain it.)

No. 5. Determination of R_1 R_0 and δ for each thermometer.

It is impossible to give any full description of the operations—I can but indicate the methods adopted.

No. 1 has already been described *supra*.

No. 2. A length of 4 c.m. of an unused portion of the bridge-wire was soldered across the thick posts supporting the coil marked FI; thus if balance was obtained with the plug FI in, its withdrawal would compel a movement of about 2 c.m. in the contact-maker to restore equilibrium. As the constitution of both wires was the same, and as they were included in the glass case, the length moved by the contact-maker was unaltered by changes in temperature.

C_1 C_2 (Fig. 1) were connected by a thick copper strip, while p_1 and p_2 were connected with the terminals of a resistance-box (r_1) having a slightly larger unit than the Kew box, and the extremities of r_1 were connected with two other boxes (r_2, r_3), of which r_2 could be altered by certain steps from 5 to 20,000 ohms, and r_3 by any quantity from 0·1 to 10,000 ohms; thus r_2 and r_3 may be regarded as shunts to r_1. All three boxes were maintained at a constant temperature.

This arrangement was adopted to enable a balance to be obtained when the contact-maker was at, or very near any given position; for example—suppose contact desired at reading + 15, r_2 and r_3 were made as large as possible, and r_1 adjusted until the bridge-wire reading somewhat exceeded 15; r_1 was then reduced until the reading but slightly exceeded 15. Reductions of some hundreds of ohms in r_3 would now cause but small alteration in the combined resistance of the three boxes, provided r_3 greatly exceeded r_1 and r_2 when in parallel arc. It was thus always found possible and easy to balance so that contact was nearer than 0·5 m.m. to any desired position.

The plug FI was now withdrawn, and the corresponding movement of the contact-maker noted. Repeated observations throughout the whole length of the wire were thus taken, not only by the writer, but also by Mr. G. M. Clark, who performed an independent series. Denote the resistance of the wire across FI by U, then the reciprocals of the observed lengths give in terms of U the effective resistance per c.m. of the wire at the middle point of each range. By means of the arrangement described above, the observations were so conducted that these middle points fell almost exactly on the integral numbers of the scale, and, by plotting, the exact values at the integers were obtained.

By repeating the process with the plug H the value of U in terms of H could be accurately ascertained, and a check was also obtained on the previous observations. The value per c.m. for the whole wire could thus be found in terms of H. Later in the operations, when the value of H was known in terms of the mean box unit, the b.-w. values were expressed in terms of the mean unit and integrated on each side of the zero mark.

No. 3. The effect of any inequality in the bridge arms of S_1 S_2 (Fig. 1) could not be eliminated by means of the Correction Tables, nor could such an error be easily detected by means of the box itself, as is the case in the remaining coils. Great attention was, therefore, devoted to securing equality. It is certain that they do not differ by 1 in 100,000.

The errors of coils A to H and FI (the temporary connection across FI having been removed) were now determined by a method originally adopted by Prof. Callendar. No great efforts were made to secure the identity of these coils with their nominal values, for it was certain that some small corrections would in any case be necessary, and as the magnitude of the correction in no way increases the labour of calculation, the time and energy expended in any exact adjustment would have been wasted.

The procedure was as follows:—

All plugs were inserted, and the balance obtained with the contact-maker at any convenient position by adjusting r_1, r_2, r_3, as previously described. H (5) was then removed, and the change in reading required to readjust balance observed. Let Z_1 be the consequent change in reading; r_1, r_2, r_3 were then altered until the contact-maker was brought back to about the same position as it occupied when H was in. H was then inserted, and G (10) removed. Let change $= Z_2$; contact was again brought to first position, D (20) removed, and G and H replaced. Let change $= Z_3$, &c.

When the process is completed we thus get a series of equations

$$A - (B \text{ to } H) = Z_8$$
$$B - (C \text{ to } H) = Z_7$$
$$C - (D \text{ to } H) = Z_6, \text{ \&c.}$$

By subtraction we then get

$$A - 2B = Z_8 - Z_7$$
$$B - 2C = Z_7 - Z_6, \text{ \&c.}$$

Now the values of Z_1 Z_2, &c., *in terms of H* are already known from the previous operations, hence A, B, &c., in terms of H can be found.

As the right-hand extremities of the intervals Z_1 Z_2, &c., were approximately in the same position, nearly the same portion of the bridge-wire was used throughout; thus any errors in the previous calibration would but slightly affect the results.

Knowing the values of all the coils in terms of H, it is then easy to express them all in terms of the mean coil, and hence in terms of the mean box unit, a corresponding correction being made in the integrations of the bridge-wire.

The zero error of the scale was next determined by reducing the resistances between C_1, C_2, and P_1, P_2 (Fig. 1) to zero, and replacing all plugs. The observations were checked by reversing all the connections. The displacement was found to be + 0·005 c.m.

No. 4. Finally the sum of all the coils was determined by means of a dial box, of whose comparison with the B.A. Standard full particulars are given in *Phil. Trans.* A, 1893, pp. 407–410. The result was that the mean Kew box unit at 20° C. = 0·0099993 Board of Trade ohms.

At the conclusion of the standardisation a large number of readings of the same resistance were taken by different observers with different combinations of coils and b.-w. readings. The accuracy of all the corrections was thus exposed to a crucial test, the results of which were satisfactory.

No. 5. The standardisation of the thermometers was performed after the installation of the apparatus at Kew, the previous observations having been made in my own laboratory.

I find that many misapprehensions are prevalent as to the nature of the operations, and it may therefore be of assistance to observers who standardise their own thermometers, if I give a complete example of one set of the observations as taken at Kew, together with their reductions. I select thermometer K_2, as several observers took part in its standardisation, and it therefore well illustrates the order of accuracy obtainable.

The numbers in italics show the corrections resulting from the standardisations of which an account has been given. The times are always entered, since the observations of the barometer cannot be taken simultaneously with the temperature measurements, and it is necessary, therefore, when working with steam and sulphur, to form a time-chart by which to ascertain the correct pressure at the moment of observation.

Thermometer K_2. *Determination of* R_0.

Date and observer.	Time.	Coils and correction.	B.-wire and correction.	Temp. box and correction.	R_0
Oct. 2, 1895					
C.T.H.	11.47	C.D.F. = + 260 + *·035*	− 2·302 + *·004*	21·38 + *·092*	257·829
E.H.G.	11.50	,,	− 2·306 + *·004*	21·36 + *·091*	257·824
W.H.	11.57	C.D.F.H. = 265 − *·023*	− 7·260 + *·022*	21·33 + *·089*	257·828
C.T.H.	12.6	,,	− 7·263 + *·022*	21·33 + *·089*	257·825
W.H.	12.13	C.D.H. = 245 + *·014*	+ 12·784 − *·059*	21·32 + *·088*	257·827
				Mean	257·827

The separate determinations were entirely independent, and taken by three different observers; the coils were so changed that the b.-w. readings altered from $-7·263$ to $+12·784$, while the sum of the corrections varies from $+0·131$ to $+0·043$, yet the greatest departure from the mean $= 0·003$.

Thermometer K_2 *in Steam.*

Date and observer.	Time.	Coils and correction.	B.-wire and correction.	Temp. box and correction.	Bar. and temp. F.	R^1
Oct. 2, 1895 C.T.H.	12.37	C.D.F.FI. = 360 − *·008*	− 2·820 + *·007*	21·30 + *·121*	29·602 at 61·2	357·300
E.H.G.	12.42	,,	− 2·824 + *·007*	21·30 + *·121*	29·600 at 61·2	357·296

The barometer reading at 12.37 corrected for temperature, and for g to sea-level, lat. $45° = 750·12$ m.m., and at $12.42 = 750·06$ m.m. (This difference of ·06 m.m. corresponds to a decrease of 0·002 in R.)

Hence mean pressure $= 750·09$ m.m., and temperature of steam at this pressure $= 99°·634$ C.

$\therefore \dfrac{347·298 - 257·827}{99·634} =$ *mean* change in R per 1° C. over this range.

Now $\dfrac{\delta pt}{\delta t} = 1 - \delta\dfrac{2t - 100}{10,000}$. We may assume δ for this wire as approximately 1·50.

Hence

$$\frac{\delta pt}{\delta t} = 0·985, \quad \therefore \frac{\delta R^1}{\delta t} \text{ at } 100° = ·9982 \times ·985 = ·983,$$

$$\therefore \delta R^1 \text{ for } 0·366° \text{ C.} = 0·360.$$

Hence

$$R_1 = 357·298 + ·360 = 357·658.$$

Thermometer K_2 *in Sulphur-vapour.*

Date and observer.	Time.	Coils and correction.	B.-wire and correction.	Temp. box.	Mean bar. and temp. F.	R.
Oct. 2, 1895 E.H.G.	1.50	A.F.G.H. = 675 − *·207*	+ 2·789 − *·013*	21·15 + *·203*		677·772
E.H.G.	1.53	,,	+ 2·796 − *·013*	21·14 + *·201*		677·777
E.H.G.	1.58	A.E. = 680 − *·089*	− 2·343 + *·004*	21·13 + *·201*	29·610 at 61·5	677·773
W.H.	2.20	,,	− 2·322 + *·004*	21·04 + *·183*		677·776
					Mean	677·775

Here, again, changes in coils and b.-w. readings do not appreciably affect the results. It is interesting to notice that the change in box temperature between 1.58 and 2.20 p.m. almost exactly accounts for the difference of 0·021 in the b.-w. readings by the different observers. As the apparatus had but just been installed, we had not got the regulator properly under control; thus the temperature changes were greater than would usually be the case.

Barometer, corrected as before $= 750·30$ m.m.

Now, b. p. of sulphur

$$= 444·53 + (p - 760) \times ·082 = 443·73,$$

and

$$pt_s = \frac{677·775 - 257·827}{357·658 - 257·827} = 420·66.$$

Hence, Eq. (d),

$$443·73 - 420·66 = \delta(4·437^2 - 4·437),$$

$$\therefore \delta = 1·512.$$

Thermometer K_2 is now completely standardised.

Constants

$$R_1 = 357·658 \quad \frac{R_1}{R_0} = 1·3872$$

$$R_0 = 257·827$$

$$FI = 99·831 \quad \delta = 1·512.$$

The most simple manner of obtaining the value of t for any given value of pt is to proceed as follows. Construct, by means of Eq. (d), a table giving corresponding values of pt and d for regular increases in t or pt, assuming the value of δ as 1·500. (For convenience of those using these thermometers, I give such a table, as an appendix, for values of pt up to 1000.) Plot the numbers thus obtained on a large scale with pt as abscissa and d as ordinate. Having experimentally found pt in a certain case with a thermometer whose value of δ is δ^1, ascertain from the chart the corresponding value of d, then $t = pt + \dfrac{\delta^1}{1·500} \times d$, and thus the same chart can be used for different thermometers.

The above example will suffice both to illustrate the general method and the standardisation of the Kew thermometers.

IV. *Concluding Remarks.*

I understand that the Kew Committee had two objects in view when they sanctioned the acquisition of this apparatus and undertook the task of directing a course of observations.

(1) To submit the methods and principles of platinum thermometry to an exhaustive trial, and especially to ascertain how far the apparatus would stand the test of time and use. Such a series of observations can only be undertaken by a department similar to that at Kew, where records are properly kept, and where the continuation of the experiments is not dependent on the life or inclination of individual observers.

(2) To establish some recognised system of standardisation for instruments intended for the measurement of high temperatures.

With regard to the latter object, I would venture to add a few remarks. If high-temperature mercury thermometers (such as those of Niehls, of Berlin) are sent for comparison, it must be remembered that the readings of these instruments are greatly influenced by the stem temperature, especially when the range is large, and it is impossible, under the conditions usually prevalent in high temperature measurements, to secure complete immersion of the stem. The observers at Kew will be able to state the length of the portion actually immersed, &c., and those who afterwards use such thermometers must endeavour, if they wish for accurate results, to reproduce the conditions as nearly as possible. The experience of Messrs. Heycock and Neville in their earlier work (when they used for their experiments mercury thermometers standardised by platinum ones)[1] shows that it is possible to reproduce the original conditions with sufficient accuracy.

Again, it is useless to standardise glass thermometers unless previous experience has shown that they are not subject to the zero rise usually characteristic of such instruments after exposure to high temperatures.

Another matter, to which I trust the attention of Dr. Chree will sometime be directed, is the suitability of platinum standards for the calibration of mercury thermometers *at ordinary temperatures*. The greatest value of d over the range 0° to 100° (*i.e.* near 50° C.) is with these standards less than 0°·4 C.; now an error of 1 per cent. in δ (and I do not believe that any such error is probable, or I may say possible) would mean an error of but 0°·004 in t at 50° C., and less at other temperatures. The readings are independent of changes in internal or external pressure, of position or of stem immersion, and are directly expressed in terms of the air thermometer. It was with a view to such comparisons that I designed K_6, which on account of the large value of FI would cause an error of ·003 in the readings to affect the resulting value of t by only 0°·001 C.

[1] *Chem. Soc. Journ.*, July 1890.

In conclusion, I may be permitted to express my gratification that the efforts made by Prof. Callendar and myself to demonstrate the accuracy and convenience of the methods of platinum thermometry are, although progress has been slow, at length awakening the attention of scientific inquirers. We believe (and that belief is founded not only on our own experience, but more especially on the work of Messrs. Heycock and Neville) that it is by means of the platinum thermometer that the many difficulties attendant on thermometric measurements, either at high or low temperatures, can be most easily surmounted.

Although the acquisition and installation of the apparatus has involved a considerable expenditure of both time and money, I am confident that, under the able direction of Dr. Chree, the results will justify the action of the Committee.

APPENDIX.

The following table gives the relation between the platinum temperature scale and the air temperature scale, when the value of $\delta = 1\cdot500$.

Platinum temperature scale.	Correction.	Air temperature scale.	Platinum temperature scale.	Correction.	Air temperature scale.
− 100	+ 2·9	− 97·1	450	+ 27·0	477·0
− 50	+ 1·1	− 48·9	500	+ 34·9	534·9
0	0·0	0	550	+ 44·0	594·0
50	− 0·4*	49·6	600	+ 54·4	654·4
100	0·0	100·0	650	+ 66·2	716·2
150	+ 1·2	151·2	700	+ 79·4	779·4
200	+ 3·1	203·1	750	+ 94·2	844·2
250	+ 6·0	256·0	800	+ 110·7	910·7
300	+ 9·8	309·8	900	+ 149·4	1049·4
350	+ 14·5	364·5	1000	+ 197·0	1197·0
400	+ 20·2	420·2			

* More accurately = − 0·375 and 49·625.

E. H. GRIFFITHS.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—It is announced that the electors to the Waynflete Professorship of Mineralogy will proceed to the election of a Professor in the course of the present year. Candidates are required to send to the Registrar of the University, on or before December 7, their applications and testimonials.

The University having accepted a bequest of £900, given by the will of the late Mrs. Fielding, for the purpose of providing for the payment of a Curator of the Fielding Herbarium, it has been decreed that there shall be a Curator of the Herbarium, appointed by the Fielding Curators, and under the direct control of the Sherardian Professor of Botany. Besides the income derived from the bequest of £900, the Curators shall have the power to apply a part of the funds at their disposal to the increase of the stipend of the Curator of the Herbarium.

The following Examiners have been approved by Convocation:—For the first examination for the degree of Bachelor of Medicine, W. R. Dunstan, G. W. S. Farmer, and Dr. R. Stockman; for the second examination for the degree of Bachelor of Medicine, Dr. C. W. Mansell Moullin, Sir William Stokes, G. E. Herman, and Dr. S. H. C. Martin. In each case the appointments are for the examinations of 1896, 1897, and 1898.

CAMBRIDGE.—Mr. T. W. Bridge, Professor of Zoology in the Mason College, Birmingham, and Mr. G. H. Bryan, F.R.S., of Peterhouse, have been approved for the degree of Doctor of Science.

Mr. C. T. R. Wilson, of Sidney Sussex College, has been elected to the Clerk Maxwell Studentship in Experimental Physics.

The late Miss Jane Saul has left her collection of shells, and the cabinet containing the same, her "Conchologia Iconica," and other conchological works, to the University.

MR. J. GAD, Extraordinary Professor of Physiology in Berlin University, has been appointed Ordinary Professor of the same subject, and Director of the Physiological Institute in the German University at Prague. Dr. M. von Lenhossek, of Wurzburg, has been appointed Prosector in the Anatomical Institute at Tübingen. Other recent appointments are: Dr. Mark W. Harrington to be President of Washington State University; Mr. H. Landes to be Professor of Geology in the same University, and Dr. H. C. Myers to be Professor of Chemistry.

DR. C. M. LUXMORE has been appointed to a Research Fellowship of the Pharmaceutical Society.

MR. JAMES WILSON, Lecturer in Agriculture, University College, Aberystwyth, has been appointed to the Fordyce Lectureship in Agriculture in Aberdeen University.

FROM the *Journal* of the Society of Arts it appears that the great advances made by Swiss national industry during the last fifteen or sixteen years, both in the technical and artistic character of its products, are attributed by the *Deutsches Handels Archiv* to the beneficial influences of State and Municipal establishments for technical education. It is very remarkable how much is done in the cantons of Geneva and Neuchatel to encourage and improve local industries, especially in finer classes of goods, for the manufacture of which a considerable amount of skill and artistic knowledge is required. In these two cantons, numbering little more than 220,000 inhabitants, there are five schools for watchmakers, and in Geneva, Neuchatel, and Chaux de Fonds there are schools for instruction in the fine arts and in artistic handicrafts. Besides the institutions there are commercial schools in Geneva and Neuchatel, and the professional schools in which instruction in various industries is given to persons of both sexes. In the watchmaking school at Geneva a class for girls has recently been established, where certain operations peculiarly suitable for female labour are taught. Considerable assistance is also rendered to the watch industry by the astronomical observatories at Geneva and Neuchatel, both by testing chronometers, and by their co-operation in the annual trade competitions.

SCIENTIFIC SERIALS.

Internationales Archiv für Ethnographie, Band viii. Heft iv. —This well-illustrated journal is steadily increasing in value and interest, as it is wider in its scope than it was at the commencement. Baron van Hoëvell, of Amboina, has a paper on a few notes on the kinds of the worship of gods in the south-western and south-eastern islands of the Malay Archipelago. Amongst other interesting information is a legend of the origin of two fetiches which are said to have fallen from heaven; one, which is called a sword, is probably a piece of old hoop-iron, and the other, a supposed spear-point, appears to be a piece of meteoric iron. There are also traces of a virginal conception through divine influence.—"Dogs and Primitive Folk" is the title of a comprehensive essay by Dr. B. Langkavel, in which he deals with dogs in folk custom and belief, the name as a term of reproach, ornaments derived from dogs, &c.—Dr. O. Frankfurter writes on dreams and their significance according to a Siamese dream-book.—J. D. E. Schmeltz has three communications on Papuan ethnography, of which the first, on objects from the Tugeri, is the most interesting. We are now beginning to learn something definite about these ruthless pirates that harass the western coast population of British New Guinea. A bow, tobacco-pipe, drum, and two remarkable dance ornaments are figured; the latter are slabs of wood carved to represent a flying bird (?), and several lizards or crocodiles. He also describes a wood-carving of what appears to be an echidna and some ceremonial objects. The rest of the journal is occupied with the usual notes and notices.

IN addition to articles specially interesting to Italian botanists, the *Nuovo Giornale Botanico Italiano* for July contains the following:—A study of the action of certain alkaloids on plants in darkness and in light, by Signor A. Marcacci. While quinine arrests the transformation of starch into saccharose, and of dextrose into levulose, both in the dark and in the light, strychnine does so only in the light, from which the conclusion is drawn that these changes are not simply chemical processes, but are dependent on other unknown forces. —On certain contrivances for dissemination in Angiosperms; in which more stress is laid than is generally the case on the action of water in the dispersion of seeds; as, for example, in the production of mucilage, to which the rupture of capsules is often due.—On the fruit of *Aucuba japonica*, by Signor L. Pampaloni.—On the affinities of the *Sphenophyllaceæ*, by Prof. G. Arcangeli. The author regards this group of fossil plants as having

no near affinity with any other, either palæontological or recent. While the structure of the stem resembles that of the *Calamarieæ*, the mode of formation of the spores is analogous to that of the *Lycopodiaceæ*.—On the development of *Tricholoma terreum*, by Signor P. Voglino.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 8.—Prof. A. W. Rücker, Vice-President, in the chair.—Mr. W. H. Everett read a paper on the magnetic field of any cylindrical coil or plane circuit. The method of treatment is based on the formula for the force due to an element of current. A single integration applied to one component of this force gives for any point in the field due to a plane circuit the force perpendicular to its plane; and a double integration gives the longitudinal force at any point due to a cylindrical coil of any cross-section, the depth of winding being supposed inconsiderable. For coils in which the latter condition does not hold, an approximate solution can readily be found. The force parallel to the plane of a circuit and the transverse force due to a coil are investigated in a similar manner. The general results are of a very simple form, and admit of easy approximate calculation. Special formulæ are deduced for coils of rectangular cross-section, the general expressions being in this case integrable. Appended to the paper are some numerical results giving the values of the forces at different points due to coils of various dimensions. Prof. Perry said he considered the paper to be a valuable one, particularly as illustrating a practical mathematical method of integrating. Mr. Trotter said the paper was of interest to him, as he considered that several of the author's results might be applied to the solution of problems on illumination—for instance, the illumination of a room by a circle of lamps. Mr. Rhodes regretted that it had not been possible to supply a proof of the paper before the meeting. The method in which the author obtained the force outside a solenoid as the difference of the forces due to two solenoids, reminded him of the method employed in calculating the attraction of, say, a truncated pyramid. Prof. Silvanus Thompson said the author had mentioned several previous papers on the subject, but had not referred to one by Prof. Viriamu Jones, in which the force due to a solenoid is obtained in terms of elliptic integrals. Another method of attack was to calculate the work done when a unit pole is carried through the solenoid and back outside to the starting-point. Prof. Ayrton said he also regretted the absence of a proof of the paper. He considered it of great importance to have exact and simple methods of calculating the forces due to a solenoid. The Chairman (Prof. Rücker) said he had made a somewhat similar calculation in connection with the magnetic effect of sheets of basalt below the surface of the earth.—Mr. E. H. Griffiths read a paper, by himself and Miss Dorothy Marshall, on the latent heat of evaporation of benzene. The method employed is similar to that used by one of the authors in the determination of the latent heat evaporation of water (*Phil. Trans.* 1895). The loss of heat due to the evaporation is balanced by (*a*) the heat supplied by an electric current; (*b*) a secondary supply due to the work done by the stirrer; (*c*) a slight gain or loss due to small unavoidable changes in temperature of the calorimeter. The comparative values of the various sources of heat (if we denote the supply due to the electrical current by 1000) is approximately:—Electrical = 1000; stirring = 11; changes in calorimeter temperature ± 5. The electrical supply could be measured with extreme accuracy, and the above table shows that small errors in the determination of the remaining thermal quantities are of little importance. The results may be summed up in the formula

$$L = 107{\cdot}05 - 0{\cdot}1981\,\theta$$

where θ is the temperature and the thermal unit at 15° C. is used. The discussion on this paper was postponed till after the reading of the paper by Prof. Ramsay and Miss Marshall, on a method of comparing the heats of evaporation of different liquids at their boiling points. The method employed has already been described before the Society (January 11, 1895). The liquid to be experimented on is put into a glass bulb enclosed in an outer jacket filled with the vapour of the same liquid. An open tube is attached to the top of the bulb, so that there is free communication between the interior and the vapour jacket, and no loss of material. Inside the bulb is a spiral of fine platinum wire, attached to stout platinum terminals which are sealed into the glass. The temperature of the liquid in the bulb is raised to the boiling point by the vapour jacket; thus when a current is sent through the wire, the whole of the heat developed is spent in converting a portion of the liquid into vapour. Two such bulbs are connected in series, and the ratio of their losses of weight is the inverse ratio of the heats of evaporation of the liquids. A correction is made for the inequality in resistance of the spirals, and the ratio of the differences of potential between the ends of the spirals, when the current is passing, is determined in each experiment by Poggendorff's method. Results are given for fourteen liquids. Prof. Ramsay drew special attention to the table giving the values of the quotient ML/T, where M is the molecular weight, T the absolute temprature, and L the latent heat. Very curious differences are noticeable in the case of water, alcohol, and acetic acid. Prof. Carey Foster expressed his admiration for the method, since it obviated the necessity of knowing the specific heat of the liquid vapour. Prof. Silvanus Thompson said the difficulty experienced in the case of water due to electrolysis might be obviated by the employment of a spiral of lower resistance and a larger current, so that the difference of potential between the ends of the spiral should be less than 1·7 volts. The Chairman said Captain Abney had asked him to inquire to what extent the temperature of the liquid was affected by radiation. Mr. J. W. Rodger asked if any direct experiment had been made to determine if the temperature of the liquid was not above its true boiling point. In some cases differences of as much as 2° might exist between the temperature of the liquid and that of the vapour given off. The differences in the value of ML/T in the case of water, alcohol and acetic acid might be due to the fact that the vapours of alcohol and water were simple, while the vapour of acetic acid was complex. Mr. R. Appleyard suggested that the differences obtained in the case of water might be due to the presence of dissolved air. Mr. Griffiths said that the objection to the adoption of Prof. Thompson's suggestion was the fear that with short wires an excessive difference in temperature between the wire and the liquid might exist. Mr. Rhodes asked if Mr. Griffiths could trust his determinations of temperature to $\frac{1}{50000}$th of a degree. Mr. Griffiths, in reply, said that he thought there was no limit to the accuracy with which a difference of temperance could be measured; the absolute temperature, however, he only relied upon to $\frac{1}{1000}$th of a degree. Prof. Ramsay said the fact of superheating existing would not affect the results, since near the temperatures at which they were working the latent heat did not vary appreciably with the temperature. In reply to Captain Abney, he said some previous experiments by Dr. Young and himself had shown that the vapour jacket was quite impervious to radiant heat from without

PARIS.

Academy of Sciences, November 4.—M. Marey in the chair.—Action of silicon on iron, chromium, and silver, by M. Henri Moissan. By heating silicon with soft iron, chromium, or silver in the electric furnace or otherwise, compounds having the composition Fe_2Si and Cr_2Si are produced by the two former metals, and silver dissolves a notable proportion of silicon, but deposits it again on solidification in the crystalline state. The silicides of iron and chromium are produced at temperatures below the melting points of either constituent, probably owing to the vapour tension of silicon at the temperature of formation; the whole process much resembles cementation. These silicides are readily attacked by hydrofluoric acid or aqua regia, slowly acted on by hydrochloric acid and unacted on by nitric acid. Fused potassium nitrate and chlorate do not act on these compounds, but they are easily decomposed by fusion with a mixture of nitrate and carbonate.—M. de Freycinet describes the aim of his book, "Essays on the Philosophy of the Sciences," of which a copy is presented to the Academy.—Elements of Swift's comet (1895 II), by M. L. Schulhof. These elements are compared with the elements for Lexell's comet given in Le Verrier's table (for $\mu = + 0{\cdot}9$), and show very near agreement.—Spectroscopic researches on the star Altaïr. Recognition of an orbital movement and of an atmosphere, by M. H. Deslandres. (See our Astronomical Column.) On the binomial differential equation of the first order, by M. Michel Petrovitch.—New method for the extraction of roots of numbers, by M. Manuel Vazquez Prada.—Expression of the pressure supported by the shaft of a hydraulic turbine at work. Theorem concerning the dynamical effect of the water. Note by M. Bertrand de Fontviolant. It is concluded that: The

dynamical effect is equal to the geometrical variation of quantity of movement suffered by the volume of water delivered per second in its passage across the turbine.—On the time distribution of rain at Athens, by M. D. Eginitis.—On the process of attacking the emerald and the preparation of pure glucina, by M. P. Lebeau.—On a group of mineral waters containing ammonia (bituminous waters), by M. F. Parmentier.—On the estimation of tannins in wines, by M. E. Manceau.—Action of chlorine on normal propyl alcohol, by M. André Brochet. Two of the products of chlorination in the cold are α chloropropionic aldehyde, $CH_3 . CHCl.COH$, and dipropyl chloropropional, $CH_3 . CHCl.CH(OC_3H_7)_2$.—On ozotoluene, by M. Adolphe Renard. Ozotoluene resembles the ozobenzene previously described. It is a white opaque mass, commencing to decompose at about 8°. It detonates on heating or by shock, but less easily than ozobenzene. Its composition is represented by the formula $C_7H_8O_6$.—Study on the nitration of menthone, by M. Konovaloff. By heating with nitric acid at 100° in a sealed tube menthone yields nitromenthone $C_{10}H_{17}(NO_2)O$. The alcoholic solution of the latter with sodium ethoxide gives a salt, undecomposed by boric, carbonic, or hydrosulphuric acids, corresponding to the acid $C_{10}H_{19}NO_4$ set free by sulphuric acid. The nitromenthone is reduced with formation of a basic substance. It is probably a tertiary nitromenthone of the composition

$$CH_3.CH\left\langle\begin{matrix} CH_2 - CH_2 \\ CH_2 - CO \end{matrix}\right\rangle C(NO_2).C_3H_7.$$

—On the fermentation of cellulose, by M. V. Omelianski. The specific ferment destroying cellulose has been isolated by the author, and is described in the paper.—Anatomy of the digestive apparatus of the Orthoptera of the family of the *Forficulidæ*, by M. Bordas.—On the application of the experimental method to the orogenic history of Europe, by M. Stanislas Meunier.—Experiments relative to the direct manufacture of pure ethyl alcohol, by the fermentation of *Asphodelus ramosus* and *Scilla maritima* with cultivated pure wine yeasts, by M.M. G. Rivière and Bailhache.—On the reclamation of the heath-lands of the Dordogne, by M. Raoul Bouilhac. It is shown that the reclamation of these sandy barrens is possible by the use of a lime phosphatic manure.—Experimental congenital deformities, by MM. Charrin and Gley.

AMSTERDAM.

Royal Academy of Sciences, September 28.—Prof. Van der Waals in the chair.—Mr. Jan de Vries read a paper on addition theorems for elliptic integrals.—Prof. Kamerlingh Onnes communicated measurements, made in the Leyden laboratory, and already published in Dr. Lebret's dissertation (July 1895) on the variation with temperature of the Hall effect in bismuth, the temperatures ranging from $-74°$ to $+240°$. Two samples of pure bismuth were experimented upon. The temperature curve of one of the specimens showed a maximum point at $-20°$; that of the other was not examined far enough. The latter specimen was melted up into a glass tube, and the variation in the electrical resistance measured between $-76°$ and $+240°$.—At the request of Prof. Cohn of Strassburg and of Dr. Zeeman of Leyden, Prof. Onnes gave an account of experiments, made partly at Strassburg and partly at Leyden, on the propagation of electrical waves in water. The result was: (1) there is no dispersion for waves of the oscillation frequency of 27 to 97 millions per second; (2) the refractive index for waves of which there are a hundred millions a second, is equal to the square root of the specific inductive capacity as measured by the statical method.—Prof. Onnes further communicated: (1) a measurement on the refractive index of glowing platinum, made by Dr. Zeeman in the Leyden laboratory. With Babinet's compensator it was impossible to establish a variation with temperature of the principal incidence and the principal azimuth, even when the platinum mirror was heated to 800° C. Hence within the limits of the errors of measurement the refractive index does not change; (2) a chart, showing the secular variation of magnetic declination, by Dr. W. van Bemmelen; (3) photographs of vibrating strings made by a new method, that of intermitting photography, by Dr. H. J. Oosting.—On behalf of Messrs. C. A. Lobry de Bruyn and W. Alberda van Ekenstein, Prof. Franchimont presented a paper on the reciprocal conversion of glucose, fructose and mannose into one another under the influence of alkalis.—Mr. van Diesen called attention to a copy, now in the library of the Academy, of the second edition of the map of North Holland, made in 1575, by order of the Duke of Alva, by Joost Jansz. Beeldsnÿder. Of the first edition no copy seems to be extant in Holland. The copy shown is the edition published in 1610 by H. A. van Warmenhuysen. Though the map seems to have been prepared with care as regards local details, the triangulation is not correct. The "mile," given as scale, probably the Spanish mile, has on this copy a length of 73 m.m.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

THURSDAY, NOVEMBER 21, 1895.

HYDRODYNAMICS.

Hydrodynamics. By Horace Lamb, M.A., F.R.S., Professor of Mathematics in the Owens College, Manchester. (Cambridge: University Press, 1895.)

THE original edition of this work, published in 1879 under the title of a "Treatise on the Mathematical Theory of the Motion of Fluids," gave the first impulse to the cultivation in this country of the modern developments of Vortex and Cyclic Motion, with their Electromagnetic Analogues, the Discontinous Jets of Helmholtz and Kirchhoff, the Dynamical Theory of the motion of perforated solids through a liquid, and the examination, as far as possible, of the effects of Viscosity. Previous writers had confined themselves to simple applications of the principle of Parallel Sections, to the bodily rotation of liquid, especially of Ellipsoids, and to simple cases of Wave Motion and of Tidal Phenomena.

The analysis invented by Helmholtz for the special case of a discontinuous jet has led, in Schwartz's hands, to important developments in the Theory of Functions, which still receive their most convincing explanation by a return to the hydrodynamical analogue. A recent article in the *Math. Annalen*, 1895, by Réthy, on this subject deserves attention. So too, in the present treatise, the author introduces much of the modern Theory of Functions, guided by considerations of physical interest; but long analytical investigations, leading to results which cannot be interpreted, have, as far as possible, been avoided.

The author quotes Poinsot's warning, "Gardons nous croire qu'une science soit faite quand on l'a réduite à des formules analytiques," as especially applicable to the present branch of mathematical physics; so he has made the analytical results convincing and intelligible by numerical illustrations, and by the insertion of a number of diagrams, drawn carefully to scale and reduced by photography. The hope expressed by the author that the results of his numerical calculations will be found correct is a natural feeling to those mathematicians who find by experience that it is no small difficulty to make use of a formula by turning its results into numbers.

The so-called practical man can use a formula in this manner, without understanding the theory upon which it is based; on the other hand the mathematical student is apt to imagine that, after the formula has been demonstrated, it is an easy matter, hardly worthy of his attention, to turn the formula to account in a numerical application, until humiliating experience teaches him his error.

The subject is opened out in the initial chapters in much the same manner as in Basset's "Hydrodynamics." The method of Conjugate Functions, now more commonly called Harmonic Functions by continental writers, is a powerful machine for the construction of results of motion in two dimensions; it is unfortunate that the method cannot be extended to three dimensions, except when the motion is symmetrical about an axis, when Stokes's stream or current function presents a certain analogue.

The hydrodynamical questions which can be solved by the system of coordinates given by confocal quadrics are very fully explained in Chapter v.; for instance, the motion of liquid due to the presence of an ellipsoid. A very slight extension of the author's method enables us to dispense with an infinite extent of liquid, and to suppose it bounded externally by another confocal, useful when the oscillations of gravitating liquid between two confocal ellipsoids is to be considered; so also the author's own investigations in the preceding chapter of the motion due to an infinite elliptic cylinder can be completed and amplified in a similar manner. We miss, too, the special consideration of confocal paraboloids, where the liquid necessarily extends to infinite distance; also the discussion of the motion of the liquid filling a rectangular box. Mr. Basset's method of exhibiting the result by two symmetrical infinite series, due to Dr. Ferrers, can be illustrated by supposing each series to represent the effect of a shearing velocity in the shape of the box, the superposition of the conjugate shear producing the same effect as a rotation.

Prof. Lamb apparently does not approve of our insular plan of collections of examples interspersed in the Chapters; but many important results, for which room cannot be found without unduly swelling the book, can in this manner receive mention, as in Basset's treatise.

The plane motion of a solid through infinite liquid is worked out completely, with accurate diagrams, in Chapter vi., the error of supposing that the path of the body can be looped when there is no circulation, is corrected; but we notice incidentally that, among all the various functions employed by the author, the elliptic functions are conspicuous by their absence. Kirchhoff's equations for the general motion of a solid of revolution in space filled with liquid afford appropriate applications of elliptic functions, especially his curious equations giving the position of the centre of the body; but these are not given in Chapter vi.

It is always gratifying to be able to utilise some result out of the vast accumulation of analysis written on the elliptic functions; attempts are just beginning at the solution of new problems in Wave Motion embodying the functions; for instance, by Willy Wien in the *Berlin Sitz.* in discussing the effect of wind, and by Korteweg and de Vries in the *Phil. Mag.*, May 1895 in extending theorems concerning the solitary wave, given (p. 420) by

$$y = h \operatorname{sec} h^2\left(x \sqrt{\frac{h}{4\sigma}}\right)$$

to the cnoidal wave

$$y = h \operatorname{cn}^2\left(x \sqrt{\frac{h+k}{4\sigma}}\right), \kappa = \sqrt{\frac{h}{h+k}};$$

reducing to the above when $k = 0$.

The author gives a complete though rather condensed account of Vortex Motion in Chapter vii., excusing himself on the ground that the recent investigations on this subject by Lord Kelvin, J. J. Thomson, Hicks, Larmor and Love, derive most of their interest from their bearing on kinetic theories of matter, theories which lie outside the province of a treatise like the present.

But Chapter viii. gives a complete and exhaustive investigation of Tidal Waves. In these cosmical problems the sailor's units are most appropriate, the sea mile or

D

sexagesimal minute of latitude and the hour; the sailor's *knot* as unit of speed can now replace the circumlocution of *sea miles per hour* of p. 274, 449, and elsewhere; but the author avoids at least the landsman's solecism of "knots an hour."

Interesting applications of Bessel functions are discussed in the chapter relating to the propagation of the tide in an estuary; it may be mentioned here that the figure for $J_0(\sqrt{x})$ on p. 295 is easily realised by revolving with appropriate speed the upper end of a vertical chain; this is the initial problem of Gray and Mathews's "Treatise on Bessel Functions."

Chapter ix. discusses the Surface Waves we are familiar with in vessels of various shapes, embodying all the results in this difficult subject which have so far been obtained. Here is a branch of Hydrodynamics which will repay the attention of young mathematicians, as every new problem solved constitutes a distinct advance in the subject; thus the determination of a state of wave motion in a canal of circular section, or in a spherical bowl, such as we see every morning at the toilet, still await solution; as also the wave motion in the gutters during a shower, when the viscosity takes a ruling part of the phenomenon.

The investigations of the effect on waves of a capillary film are easily extended to the case where the film possesses a certain superficial density, as a flag or sail, for instance, or

"—the winning wave deserving note
In the tempestuous petticoat,"—

and where the film possesses flexural rigidity, as a sheet of ice; thus the results of Kelland, Kirchhoff, and others on waves in canals are but slightly modified when the free surface is supposed to be frozen. The minimum wave velocity, where the ripples change into waves, is now shown very elegantly by Mr. C. V. Boys on a logarithmic diagram (NATURE, July 18, p. 273).

Sir George Stokes's theory of Group Velocity of Waves, introduced modestly in a Smith's Prize Question, and developed subsequently by Osborne Reynolds, has cleared up much of the mystery of the turbulence of sea waves, and explained the reason of the sailor's adage that every ninth wave is a big one, or every third wave in crossing a bar; for on this theory, if every mth wave is a big one, the motion is principally due to the superposition of two trains of waves, whose lengths are in the ratio of $(m - 1)$ to $(m + 1)$.

The author summarises very clearly the researches of Lord Kelvin and Lord Rayleigh on the wave-making due to the motion of a ship, and the complicated pattern produced in the wake of a steamer, of a duck, or even of a stick drawn through the water is illustrated in diagrams on pp. 402, 403. If the unpublished investigation referred to in the footnote of p. 403 relates to the explanation of the curious appearance of the echelon bow waves which form the fringe of the wake, where the wave fronts make an angle with the keel, the tangent of which is double the tangent of the angle between the wave fronts and the general direction of the echelon, the following extract from a letter by Lord Rayleigh will supply the deficiency:—

"A train of waves keeping up with a boat moving along Ox with velocity V_0, the crests making an angle θ with the keel, will be given by

$$a \cos k\,(Vt - x \sin\theta - y\cos\theta)$$

where

$$V = V_0 \sin\theta;$$

and the groups are due to the combination of two such trains, defined by k, $k + \partial k$; V, $V + \partial V$; θ, $\theta + \partial\theta$; subject to $V \propto \lambda^{\frac{1}{2}} \propto k^{-\frac{1}{2}}$, or $k \propto V^{-2} \propto \operatorname{cosec}^2\theta$.

The resultant is thus given ultimately by

$$2a \cos k(Vt - x\sin\theta - y\cos\theta)$$
$$\cos \tfrac{1}{2}\{\delta(Vk)t - x\partial(k\sin\theta) - y\partial(k\cos\theta)\};$$

so that if the line of echelon makes an angle ϕ with the keel,

$$\tan\phi = \frac{\partial(k\sin\theta)}{\partial(k\cos\theta)} = \frac{\delta(\operatorname{cosec}\theta)}{\delta(\operatorname{cosec}^2\theta\cos\theta)} = \frac{\tan\theta}{2+\tan^2\theta}$$

or

$$\tan(\theta - \phi) = \tfrac{1}{2}\tan\theta."$$

("Progressive Waves." By Lord Rayleigh. *Proc. London Math. Society*, vol. ix.)

Chapter x. on Waves of Expansion discusses some problems, such as oscillations of the atmosphere, but passes over the applications which belong more properly to the Theory of Sound.

To account for many observed hydrodynamical phenomena, notably of the passage of a ship through the water, the hypothesis of perfect limpidity, postulated in Chapter i., must be abandoned, and the equations of motion, such as those employed by Osborne Reynolds in his investigations on turbulent motion and skin resistance, become complicated to a formidable extent. It is, however, in this direction that the most useful line of attack on new and practical problems must be directed.

The book concludes with Chapter xii. on the Equilibrium of rotating masses of liquid, such as the spheroid of Maclaurin and the ellipsoid of Jacobi, and with a slight sketch of Poincaré's investigation of the secular stability, and of the kindred researches of Bryan and Love.

Considering that the author has already developed the requisite Spherical Harmonic analysis, we think that a *résumé* of the theory of a Figure of the Earth would have occupied very little space, and would have been very welcome, as Prof. Adams's lectures on this subject are not yet generally available.

Prof. Adams led up to Laplace's general case of strata, varying continuously in density from one to the next, by an examination of the particular cases of a spheroid composed of two, three, or more strata of uniform density; so, too, the examination of the possibility of a permanent distribution of the strata in the interior of an ellipsoidal shell which is rotating about any fixed diameter, is worthy of a careful examination by a young mathematician as an interesting research; the oscillations of such a shell have already been considered by Mr. S. S. Hough (*Proc. R. S.*, February 7, 1895).

A comparison between the present treatise and Basset's Hydrodynamics is interesting from the different modes of presentation of parts of the theory; we have reason to be proud of both as representing a branch of mathematical investigation in which foreign experts pay us the compliment of conceding that we are capable of teaching them something. A. G. GREENHILL.

GREEK TRIBAL SOCIETY.

On the Structure of Greek Tribal Society. An Essay. By H. E. Seebohm. (London: Macmillan and Co., 1895.)

In this scholarly and modest essay, the author has collected some of the evidence relating to a certain stage in the development of Greek society, the existence of which runs some danger of being insufficiently recognised by students of ancient history. "Greek" society to most people means, in the first place, the society described in the Homeric poems; in the second, Athenian society from the fifth century downwards. These limitations of the field are the natural outcome of the paramount importance of Homeric and Athenian literature; information as to the structure of society in other parts of Greece and at other periods of Greek history can, with a few exceptions, only be gleaned from incidental references in Homer and the Attic writers, and from the data afforded by comparative anthropology. To a certain extent Mr. Seebohm's field of observation may still seem to be somewhat confined, and his work would have been more valuable had the few facts known of the life of the less civilised parts of ancient Greece been more extensively utilised. To this end we could, perhaps, have spared some of the detailed discussion of the better-known survivals of tribal institutions in Athenian society of the fourth century.

Within these limits, however, Mr. Seebohm's treatment of the subject merits little but praise. His employment of the comparative method is throughout judicious. Outside the Greek world, he has utilised three main sources of information—the Old Testament, the Ordinances of Manu (a code going back in its present form probably to the fifth or fourth century B.C.), and the Welsh law. The selection, as he admits, is arbitrary, particularly in the exclusion of the Roman system from the field of comparison. But the highly-organised character of the latter is a source of danger when it is used for comparison with the looser structure under consideration, and its exclusion is therefore somewhat of a relief.

Most investigations of the structure of ancient political systems must begin with Aristotle. His treatise on "Politics," however, deals with society in its highest stage, with man's activity *τοῦ εὖ ζῆν*, not merely *τοῦ ζῆν ἕνεκα*. It is with the previous stage that we are here concerned; in fact, with what he calls "village" life—the "village" being a convenient term for the union of families, whether living close together or not, just as the state, or political union, is the combination of "villages," whether within one city-wall or scattered about a district. This "village" life has four main characteristics. As society begins in the family, the first and most important, on which all the others depend, is the bond of kinship. Secondly, the body must be organised, and this necessitates a government. The permanence of the society is maintained in two ways—by the cultivation of the land, and by the worship of the gods; in the first place those of the family, in the second those of the community. As the village is merged in the state, which reproduces on a larger scale, and therefore in a less intense degree, the relations of early society, the order of things is reversed. But the old relations continue to exist within the larger group, and it is these still-existing tribal elements that we have to trace in the complex political society.

Mr. Seebohm's work falls into two main parts, dealing with the nature of kinship, and the relation of the family to the land, thus approaching the subject from the point of view of the first and third characteristics mentioned above. Undoubtedly this is a more scientific method than that (identified with the name of de Coulanges) which commences with the religious union, or that which lays most stress on the system of government. Primitive man is not in the first instance religious; his religion is only one of the forces which he brings into play to preserve his family or tribal unity; and government is another such force. The cultivation of the land, again, is of the first necessity, unless the tribe subsists on plunder. Any properly historical investigation should therefore begin with these two matters.

With regard to the nature of kinship, a great deal of information can be extracted from the private speeches of the Attic orators. Into this part of the subject, as we have already said, Mr. Seebohm has gone very fully. Two points seem to be of special importance, the supremacy of the head of the family, and the limitation of the "inner-circle" or *ἀγχιστεία*, the group of blood-relations, "responsible to each other for succession . . . for vengeance and purification after injury received by any member, and for all duties shared by kindred blood." As regards the nature of the government of the group, there is one feature which might perhaps have been dwelt upon a little more than it has been; that is, the limitation of the supremacy of the head of the family. Every household was ruled by its oldest member; but at the same time a passage from Plato, quoted by Mr. Seebohm himself (p. 60), shows that certain measures, such as the disinheritance of a member of the family, could not be undertaken without the consent of the kindred: "He who . . . has a mind . . . to expel from his family a son . . . shall collect together his own kinsmen, extending to (first) cousins, and in like manner his son's kinsmen by the mother's side, and in their presence he shall accuse his son, setting forth that he deserves *at the hands of them all* to be dismissed from the family." This family-council is an important factor in tribal life, particularly as being the prototype of the council of the city-state, which, as already remarked, only reproduces on a larger scale the relations of the previous stage of society.

In limiting the *ἀγχιστεία* to the degree of great-grandson, Mr. Seebohm seems to be quite right, although there are authorities who interpret *παῖδες* in the crucial expression *ἀνεψιῶν παῖδες* as meaning not merely children, but descendants. The evidence afforded by the litigation between the members of the family of Bouselos, which is excellently described on pp. 62 *ff.*, seems to make this clear.

The closeness of family relations in Greece gave rise to a curious state of things as regards the position of the illegitimate child. The position of the *νόθος* is perhaps not quite clearly stated by Mr. Seebohm. In one sense he had no place in the kindred. He could not be admitted to the phratria without the consent of the true son. The laws of Solon allowed no right of inheritance to the bastard, except in the case of failure of legitimate heirs. (It is true that the scholiast on the

passage of Aristophanes where this law is quoted thinks it is an invention of the poet's. But in any case the invention was probably founded on fact). In the text of the speech of Demosthenes against Makartatos is a law dating from Eukleides (403 B.C.), which seems to refuse to bastards even the limited right granted by Solon, as nothing is said of the case of legitimate children failing. But it is unwise to press the interpretation of the laws quoted in the speeches of Demosthenes, as they are notoriously in most cases interpolations of a later date. In any case it is clear that under ordinary circumstances the bastard could not be ἀγχιστής in his father's family. He could only claim as inheritance the νοθεῖα, which was a very limited sum. But this must not be interpreted in the sense that he was altogether an outcast. Politically he suffered little. Gilbert ("Greek Constitutional Antiquities," Eng. trans. p. 191, note 1) believes that νόθοι *ex cive Attica* were *ipso facto* citizens. When both parents were citizens, the bastard would probably belong to the Phyle of his mother, and when of age would be admitted to her Deme. The position of the bastard, however, brought into play the same device for evading the law as that suggested by our new death-duties, and wealth, as the scholiast already quoted informs us, was made over by the father by gift before his death. Greek society thus did something to alleviate the lot of the illegitimate son, whose position in the family, or rather out of it, might otherwise have been somewhat hard.

Mr. Seebohm is nervous lest, in ascribing to the structure of Athenian society a direct parentage amongst tribal institutions, he should meet with considerable criticism. It is improbable that any one will dispute his main conclusions. At any rate he is sensible of most of the difficulties attaching to his subject. There are many features in Greek society which seem foreign to the tribal system. The absence of Homeric evidence for regular ancestor-worship is not very satisfactorily explained by the suggestion that "the aristocratic tone of the poet did not permit him to bear witness to the intercourse with any deity besides the one great family of Olympic gods, less venerable than a river or other personification of nature." The Homeric poems, especially the Odyssey, are too full of the small details of daily life to permit us to accept this explanation—for Homer deals with swineherds as well as kings. Or take, again, the question of burial. De Coulanges ("La Cité Antique," p. 68) states roundly that the ancient custom was to bury the dead, not in cemeteries or by the way-side, but in the field belonging to each family. He adduces evidence for the survival of this custom even in the time of Demosthenes. But if this was the rule, what are we to say of the innumerable cemeteries dating from all periods, prehistoric downwards, which have been discovered all over Greece and on the islands and shores of the Aegean? In some parts, such as Lycia, we find the true tribal system of burial in use down to late times; but it is hardly an exaggeration to say that this is exceptional.

The essay before us touches on several questions of this kind, but space doubtless prevented the author from dealing with them at greater length. It is to be hoped that he will continue this line of study, and produce the volume dealing with Roman customs to which he alludes in his preface.

G. F. HILL.

A BIOLOGIST AS METAPHYSICIAN.

Mind and Motion and Monism. By the late George John Romanes, M.A., LL.D., F.R.S. Pp. vii. + 170. (London: Longmans, 1895.)

THIS little volume of Mr. Romanes' metaphysical writings possesses great interest. The type of philosophical theory which he represents has a singular fascination. He himself, it is plain, possessed genuine metaphysical powers, and he wrote at first hand, and with the acuteness and freshness of mind which are worth more than much learning. At the same time, he suffers for his disengagement from the work of other philosophers. The *naïveté* which forms the opening sentence of the book, that Hobbes is "the earliest writer who deserves to be called a psychologist," is a trifle. But there is no evidence that he had studied the father of monists, Spinoza; and though some points in his essay might have been modified if he had lived, it presents difficulties which, to a student of Spinoza, seem to be of the first magnitude. Yet, like the rest of his philosophical writing, even when it is unsatisfactory (and it seems to us unsatisfactory), it stimulates thought.

The volume consists of two essays, the Rede Lecture of 1885 on Mind and Motion, and a longer treatise on Monism, which amplifies and expounds the metaphysical ideas of the earlier essay, but makes many additions. Romanes holds with Clifford (who seems to have inspired his speculative thinking) that wherever there is matter there is mind in some form or other, and that mind and matter are everywhere but two aspects (two modes of apprehension he calls them) of one and the same reality. He makes admirably clear the truth that a physiological process which is accompanied by consciousness would not be what it is, if it were unaccompanied by consciousness, any more than we can separate the light and heat of an Edison burner. He shows that if we apply the idea of causality to mental action, we must apply it to the twofold reality, which is both physical and mental. But he throws no light on the difficulties raised by the phenomena of so-called unconsciousness. His disproof of spiritualism, as implying a creation of energy, is satisfactory; his disproof of materialism is less so. It is a shorter way with the materialists than even Berkeley's. To treat mind as a function of matter would be to treat it as a function of itself, since all that we know of the external world is our own mental modifications. Whereas Berkeley held matter to have no existence, save as an object of mind, Romanes goes further, and regards it as in some way mind itself. But if one fact is clearer than another, it is that we rarely have knowledge of our mental states, and that we primarily know objects. On the other hand, the simpler solution, that a physical process which is accompanied by consciousness cannot be merely physical, would afford no foundation for the theory of monism.

The most interesting portions of the essay are those in which he goes beyond Clifford. Clifford had stopped with attributing to each part of matter some portion of mind, mind-stuff, but said nothing of the universe itself. Romanes holds that we may regard the whole world of objects as itself an eject (*i.e.* an inferred subject), which we may regard as super-conscious. He founds himself on

the idea of a social consciousness working in the minds of members of a society. Though in his idea of an absolute mind he approaches most nearly to Spinoza, the argument is totally different, and the difficulties it raises are overwhelming. Is such a mind finite or infinite? If finite, where are the bounds of matter? If infinite, the analogy from the minds we know, which accompany a limited portion of matter, breaks down. Of a social mind we know nothing in fact; but so far as we conceive it clearly, we conceive it as animating the minds of individual persons. Yet if it is to supply a basis of inference to an absolute mind which animates the whole universe of physical and material things, we must suppose it to animate not merely ourselves, but our houses and all the material of our social life.

Romanes' thought reaches its highest flight where he identifies the principle of causality with volition. By this means he seeks to maintain the freedom of the will, and to find an explanation of morality and responsibility. It is an argument of much subtlety and ingenuity, in which elements are blended that remind us partly of Kant, partly of Green, but never of Spinoza. It culminates in an interesting theistic speculation, in which the absolute will is represented as assenting to the free volitions of all relative wills. The basis of the argument is a protest against regarding causality as in any sense prior to the mind, so that the mind should be subject to determination. The consciousness of causality is derived from volition, and therefore, so he seems to argue, volition is the primary cause. Hence the will as will is free to will anything whatever, even the impossible—it is limited only in its executive capacity through the restraints imposed on the body. On the other hand, though every will is free and might have willed otherwise, the moral or rational will is that which wills what is expedient under the circumstances in which actions have to be performed in the external world. This is no restriction of freedom, any more than a man is not free to marry, because to do so he must go through the marriage ceremony (a strange re-emergence this of the notion that moral action is simply self-consistent action). The questions raised by the argument are seductive. Every reason which Romanes alleges for the freedom of mind, as unaffected by causality, is equally an argument on the monistic theory against the causal necessity to which matter, he believes, is still subject. Instead of holding mind free and matter bond, he should have held them both equally bond or equally free, or should have declared causality to be an illusion. As it is, he has in reality reintroduced the notion of a mind which is not even affected by its own character. And this on the ground of what seems to be a confusion between two interpretations of will, as the process of which we are aware in volition, or as some supposed activity behind volition itself. If causation and volition are identical, as he says, and we become aware of causation by volition, the will must be the process known. But this may surely be subject to causality, like any other object of thought. If the will is understood in the other sense, how are we to understand the monistic identity of mental state and physiological process? Elsewhere Romanes urges that the mind is free, since whatever acts upon it is recognised by it as a motive. It would seem then natural to hold that while minds as well as bodies must be regarded as subject to determination, i is only minds which are conscious of their motives, an which therefore may have the consciousness of freedom.

OUR BOOK SHELF.

Farm Foods: or, the Rational Feeding of Farm Animals. By Emil v. Wolff. Translated by Herbert H. Cousins, M.A. Pp. xvi. + 365. (London: Gurney and Jackson, 1895.)

This is a translation from the sixth edition of the well-known "Landwirtschaftliche Fütterungslehre" of Prof. v. Wolff, of Hohenheim. The book embraces three sections, dealing severally with the general laws of animal nutrition, the food of farm animals, and the feeding of farm animals. The most valuable part of the volume is the appendix which consists of a series of six tables relating to (1) the average composition and digestibility of farm foods; (2) the digestibility of food-stuffs; (3) the nitrogen of foods expressed as albuminoids and amides; (4) feeding-stuffs for farm animals; (5) percentage composition of different parts of oxen, sheep, and pigs; (6) composition of carcase of oxen, sheep, and pigs. It is a coincidence that the volume should have appeared at about the time when the plaint went up at the meeting of the British Association at Ipswich, that for purposes of teaching or calculation we have to employ the results of German analyses relating to crops and food grown in a different climate, and under different conditions, from our own. In this way expression was given to the fact that the essential parts of Wolff's tables could be found in English books any time within the last eighteen or twenty years, so that agricultural students who were unable to read Wolff's work in the original were, nevertheless, not greatly handicapped. The circumstance that Wolff's investigations have in this way been so thoroughly "exploited" by English writers will no doubt impair the freshness and originality such as would have been associated with a translation of the treatise when it first appeared in 1874.

The examples that are given have a distinctly Teutonic flavour, and we may be pardoned for saying that, from our standpoint, they are somewhat academical. English farmers know nothing, for example, of potato slump, and Scotch farmers have to fatten their bullocks without mangel. Yet German beef is not to be mentioned in the same breath as the prime juicy joints of British growth, and German farmers have yet to bring their practice up to the level of turning out finished steers at three years old. A problem of far greater interest than any of those discussed would have been: Given a breeding flock of 500 or 1000 ewes to carry through such a season as either of the last two winters in Great Britain, with frosts severe and forage scarce, how would it best be done? English sheep-breeders solved this problem, and if they study this volume they will without doubt give due weight to the words (p. 105): "it is evident that our methods for the chemical analysis of food-stuffs, as well as our knowledge of the peculiar properties and proportions of different food-constituents, leave much to be desired."

The translator has done his work carefully, but he is not happy in his prefatory remarks, which show a lack of familiarity with English agricultural literature. When he refers to "the rather obtrusive fact that the book is simply the record of forty-two years' work by the experimental stations of the German Government on the feeding of farm animals," and further on says that "perhaps the most valuable feature of the book is that of the tables given in the appendix," he apparently overlooks the circumstance that at least two of the six tables are, as is acknowledged by Wolff himself, based principally on the results of Lawes and Gilbert, as published in the *Philosophical Transactions* in 1859 and 1883. But the reader will be prepared to overlook much when he sees

that even the name of Rothamsted is misspelt, both in the text and in the index. That Wolff's work, in English dress, will serve to increase the fame of its author cannot for a moment be doubted, and it is much to be hoped that many of the intelligent readers into whose hands it may fall will be qualified to read the volume critically.

Dog Stories from the "Spectator." With an Introduction by J. St. Loe Strachey. Pp. 264. (London: T. Fisher Unwin, 1895.)

A FEW of these stories record reasonable and well-observed instances of intelligent and deliberate acts of dogs, but most of them are anecdotes in which a modicum of fact is lost in a plenum of anthropomorphic fancies.

When an animal does anything remarkable, the average man (and more so the average woman) conceives that it is guided to its action by a train of *human* reasoning. It must, of course, be granted that dogs often behave with exceptional intelligence, and perform acts with distinct ends in view; we do not, indeed, venture to doubt any of these stories from the correspondence columns of the *Spectator*. But few people seem to be able to separate the "what" from the "why" when writing of animals' actions. Well-authenticated and trustworthy notes on canine intelligence are valuable; but when the narrators essay to explain the dog's motives, they get out of their depth. Here is the gist of a story of this kind: A dog jumped into a carriage at one of the stations on the District Railway; it remained under a seat of the compartment when the train stopped at two stations while the carriage door was opened, but when the door was opened the third time, the dog jumped out and slunk away. There is no evidence whatever that the dog's act was deliberate; and unless there were proofs to the contrary, it must be assumed that it was simply the result of impulse. Yet the anecdote fills nearly two pages of the book, the writer assuming that the dog recognised the station at which it alighted, and concluding with the words: "I suppose that he had been transferred to a new home, which had proved uncongenial, and was slipping away, in fear and trembling, to his old quarters." This is a fair example of the sentimental type of dog story—a type which predominates in the collection before us. A man who knows how to observe in a scientific manner, has no patience with the crude statements and unsupported assertions which make up most of these epistles; he will put his finger on weak points in nearly every page of this book. Many of the facts are the results of coincidences, but here and there among the chaff will be found grains of information of real importance to students of the instincts and habits of animals. The value of the stories is largely discounted from the scientific point of view, by the fact that the writers are often anonymous.

Science Readers. By Vincent T. Murché. Books v. and vi. (London: Macmillan and Co., 1895.)

THESE books are intended to be read by pupils in elementary schools, in conjunction with "object-lessons" given by the teacher. The text has been so carefully prepared, that juvenile readers will have no difficulty in understanding it, while the profuse illustrations add to its attractiveness. The apparently indiscriminate distribution of the subjects of the reading lessons is not one that commends itself to those who regard the orderly statement of facts as the cardinal principle of scientific instruction; but it must be remembered that pupils have to be interested as well as instructed, and Mr. Murché's practical knowledge of what interests the young people for whom he writes, has led him to depart from a strictly scientific arrangement. Putting this aside, however, the books contain a large amount of useful information, which the elementary scholars who read them will easily acquire.

The November Meteors.

FROM various observations it would appear that the Leonids have not presented any unusual activity this year. The weather was tolerably favourable on the nights of November 12, 13 and 14, though there were occasional clouds and showers of rain; meteors were not, however, particularly numerous at any time.

At Bridgwater, on November 12, Mr. Corder watched the sky during the period from 14h. 5m. to 16h. 30m., and observed eighteen meteors, of which three or four only were Leonids.

At Bristol, on November 13, the writer counted ten meteors between 11h. and 13h. 30m., of which two only were Leonids. The sky was, however, partly overcast. At Bridgwater Mr. Corder maintained a look-out between 14h. and 16h. 10m., and recorded twenty-six ↙'s, including eleven Leonids with a well-defined radiant at $152° + 23°$.

At Bristol, on November 14, the writer saw very few meteors, and no Leonids before midnight. The observations were, therefore, relinquished as not likely to be productive.

During the nights following the 12th and 13th, and on the early part of that of the 14th, it is certain, from the above notes, that the Leonids were not numerously visible. If, therefore, the earth passed through a region of the stream much denser than usual, the *rencontre* must have occurred during daylight on the 14th. Observations in America will probably allow this point to be determined.

One of the best of the mid-November meteor showers has its radiant in Taurus, and it is a stream which furnishes an unusual proportion of fireballs. Several of them have been observed in the present year. About ten Taurids were seen at Bristol on the nights of the 13th and 14th, and Mr. Corder says that on the 12th and 13th he found them rather active and diverging from an accurately marked centre at $58° + 22\frac{1}{2}°$.

Fireballs appeared on November 9 at about 8h. and 10h. 45m. p.m., and on November 11 at 6h. 2m. p.m. Several conspicuous meteors were also remarked on the early evening of November 14. W. F. DENNING.

Bristol, November 17.

P.S.—A communication just received from Dr. A. Riggenbach, Professor of Astronomy at the University of Basle, Switzerland, contains the following:—"On November 13, after heavy rains the sky cleared up, and during the hours from 9h. 40m. to 13h. I perceived fourteen meteors, but only two of them appeared to be in connection with the Leonid swarm. From 1h. in the morning of the 14th, clouds impeded the observations. On November 14–15 the sky was overcast." Dr. Riggenbach's experience would therefore appear to corroborate the meagre results obtained at Bridgwater and Bristol.—W. F. D.

A Remarkable Daylight Meteor.

JUST before five in the afternoon of Wednesday, the 13th inst., a meteor of rare brilliancy, evidently one of the Leonids, was seen here. It was as large as Venus at its best. When flashing into view it lighted up the landscape with startling effect, though daylight had not faded. The meteor was followed by a dazzling golden-coloured train, which lasted for several seconds. The colour of the meteor by the waning daylight was of a peculiar greenish-blue tint.

Owing to the large size and intense brilliancy of the meteor, I expected that its grand appearance would have been observed in some other locality and noted in NATURE. Here this season the stream of the Leonids has been little in evidence.

Worcester. J. LLOYD BOZWARD.

The Feeding-Ground of the Herring.

IN your issue of October 24, Mr. Alexander Turbyne takes exception to the belief that copepods are most abundant between the Laminarian zone and the 20-fathom line. He gives his experience to prove that they congregate chiefly "in the deep water over the mud," and his contention is that herrings found with great numbers of copepods in their stomachs feed, for the

most part, at considerable depths, as in the depressions of 70 to 90 fathoms found in Loch Fyne.

I notice that this letter has now been reported in the *Fish Trades Gazette*, and, fearing lest the statement should go further unchallenged, I should like to suggest that the experiences of Brady, Herdman, and Scott cannot be set aside lightly. I in no way doubt the statement that copepods are abundant on the mud at 70 fathoms, but from the evidence given it is surely unnecessary to conclude that such depths are the natural feeding-ground of the herring. In Loch Fyne, after continued calms, I have seen congregations of *Calanus finmarchicus* floating in belts of dull opaque yellow, or left by the tide in such masses as made it possible to scoop them up in one's hand. It is far from probable, I fancy, that Mr. Turbyne's deep-water forms were more abundant, and yet the question is not merely one of the vertical range of copepoda. That herrings descend to a considerable depth seems true. That their eggs will hatch at as great a depth of 95 fathoms, the late Mr. George Brook and I proved in Loch Fyne. If at certain seasons they tend to congregate in deep areas, it is fortunate that, as Mr. Turbyne shows, a favourite food is to be had; yet when the copepods were as I describe, I saw the herrings being caught near the surface—I spent many nights off Skippness Point and in Kilbrennan Sound—and the fishermen told me that beneath such floating belts of copepods, closely packed shoals are usually to be met with. The fishes taken were gorged with *Calanus* and a few other species, such as *Temora longicornis* and *Dias longiremis*. The so-called disease of gut-pock was then prevalent. This I attributed, rightly or wrongly, to excess of oil brought into the intestinal tract by the copepods. The oil extruded plentifully from the anal openings. This, then, is evidence of herrings feeding freely on a plethora of copepods near or on the surface; evidence of a similar kind to that of Mr. Turbyne's, yet with an opposite deduction.

W. L. CALDERWOOD.

Napier-road, Edinburgh, November 11.

MacCullagh's Theory of Double Refraction.

IT is quite clear that Mr. Larmor has misapprehended the purport and object of the criticisms in my letter to NATURE of October 3.

I have not attempted to discuss the question whether or not "a gyrostatic ether may be constructed which will function (*sic*) according to MacCullagh's optical scheme." What I have said, is that the theory advocated by Mr. Larmor violates the principle of angular momentum, which is a totally different thing. I have also carefully avoided making use of any such phrases as "ordinary elastic matter," "elastic solid matter," and the like; for the employment of such expressions with reference to a quasi-fluid medium of extreme rarity, such as the ether is supposed to be, is altogether misleading, and is responsible for a good deal of misconception upon the subject.

Ever since the undulatory theory was accepted by the scientific world, the object of mathematicians has been to endeavour to form a conception of a medium whose properties are such, that optical phenomena may be deduced therefrom by dynamical principles and methods; and in order that any attempts should be successful, it is necessary for the medium to possess inertia, and also to be capable of resisting deformation. The latter condition requires that the forces on any right solid element, which are due to the action of contiguous parts of the medium, should consist of nine stresses. Now, whatever physical properties we may ascribe to the ether, or whatever the mathematical form of the equations may be which connect the nine stresses with the quantities upon which deformation depends, the principle of angular momentum requires that three relations should exist between the six conjugate stresses, except in the two special cases I have referred to in my former letter; that is to say, unless the medium is a gyrostatic one, or unless it is under the action of some system of forces (mutual or otherwise) whose action upon an element consists of a couple as well as a force.

Mr. Larmor appears to think that a satisfactory solution can be obtained by postulating an energy function, and deducing the equations of motion and the boundary conditions by the principle of least action; but this view is fallacious. For if some particular form of the energy function were assumed, and were found to lead to results which violate the principle of angular momentum, the theory would be dynamically unsound, and the results would represent some impossible form of motion. To write down certain mathematical expressions, and to perform certain mathematical operations, do not constitute a satisfactory theory, unless it can be shown that all the results furnish a consistent scheme in which none of the fundamental principles of dynamics are violated.

Mr. Larmor also suggests that possibly the energy function of a gyrostatic medium might be modified[1] in such a manner that MacCullagh's equations might be deduced therefrom by means of the principle of least action, and that it would be interesting and instructive to establish this in detail. But why has this not been done? If a mathematical investigation of this kind would be unsuitable for NATURE, the same objection would certainly not apply to the *Philosophical Transactions*.

I shall defer entering fully into the subject of magnetic action on the present occasion; but in the paragraph marked (2), Mr. Larmor has altogether failed to deal with the objection which I advanced, viz. that his theory is open to exactly the same defect as my own, inasmuch as it makes the tangential component of the E.M.F. discontinuous at an interface. What, according to Mr. Larmor's view, is the mathematical expression for the E.M.F. in a magnetised medium? What is the physical interpretation of the boundary condition referred to in my second letter? Does he propose to modify Maxwell's equations connecting the E.M.F. with the electric displacement? If he does, he ought to have stated the fact, explained the nature of the modifications he proposes, and his reasons for adopting them.

In conclusion, I fail to see that Mr. Larmor has made any adequate reply to my criticisms. To do this he must show (1) that his resuscitation of MacCullagh's theory does not violate the principle of angular momentum; (2) that his magnetic theory makes the tangential component of the E.M.F. continuous at an interface.

A. B. BASSET.

Fledborough Hall, Holyport, Berks, November 12.

1 The theory of the mixed transformation of Lagrange's equations, which leads to the energy function alluded to, was first given by myself in 1887. (See *Proc. Camb. Phil. Soc.*, vol. vi. p. 117, and "Hydrodynamics," vol. i. p. 173.)

The Nomenclature of Colours.

THE letter of Mr. Herbert Spencer in your issue of August 29, suggesting the use of a nomenclature to be used in connection with a scheme of colour standards, on a plan similar to that used by sailors in boxing the compass, is interesting, both because of its obvious appropriateness and because, as Mr. Spencer suggests may be the case, it has occurred to others. In a paper read before the American Association in 1890, I suggested the same idea, but at the same time stated that this would probably give more hues between the six standards than would be convenient in view of the uncertainty that will almost surely result in the mind of the common observer as to just which term should be applied in any one particular case. In view of this, I thought it wise to make the number of hues between the standards smaller than the compass chart would give. Those who have applied the standard colours to educational work have found this desirable.

The Milton Bradley Company, in their educational series of colour papers, have introduced only two hues between the standards. This makes the series R OR RO O YO OY Y GY YG G, &c. Mr. Louis Prang, of Boston, some two years since published a small pamphlet, proposing to make the series for common use R RRO ORO O OYO YO YYO Y, &c. On the whole, I think it wise to adopt the smaller number for ordinary use, and interpolate others for more delicate discriminations. A plan which seems to me a very practical one is the following, in which the hues represented by the symbols in capitals are for ordinary use, and those in small type for more careful discrimination: R orr ror OR oor rro RO oro roo O yoo oyo YO yyo ooy OY yoy oyy Y, &c. Translated into words, this would be RED, orange-red red, red orange-red, ORANGE RED, orange orange-red, red red-orange, RED ORANGE, orange red-orange, ORANGE, &c. Whatever method is used, however, does not in any way affect the value of the scheme of definitely determined standards of colour as proposed in my paper.

J. H. PILLSBURY.

Stoneham, Mass., U.S.A., November 7.

THE *Scientific American*, of New York City, in its issue of October 19, 1895, quotes from a letter to NATURE (vol. lii. p. 413), written by Mr. Herbert Spencer, suggesting that a

system of colour nomenclature might be devised by indicating colours in a manner analogous to the accepted nomenclature of the points of the compass.

In this connection the enclosed circular, published by me during the summer of 1893, to explain briefly my system of colour standards, may be of interest to your readers. You will see that the system of colour nomemclature here described corresponds almost precisely to the idea in Mr. Spencer's mind.

October 24. LOUIS PRANG.

[WE have received, with Mr. Prang's letter, the circular descriptive of his system, which is essentially the same as that suggested by Mr. Spencer. As Mr. Spencer pointed out in his letter to us, the idea is a very obvious one, and had probably occurred to others; but this does not, of course, diminish its value. For ourselves, we are glad to see that the idea has been put into practice, and that, out of a chaos of colour-names, an intelligent system of nomenclature has been evolved. A series of standard coloured papers, harmoniously bound together, is published by the Prang Educational Company, Boston, for the use of teachers, designers, artists, and others.—ED. NATURE.]

RECENT IMPROVEMENTS IN LIGHTHOUSE ILLUMINATION.

PRIOR to the year 1822, the optical apparatus used in the best equipped lighthouses was silver-plated parabolic reflectors, having apertures, twenty-one inches for fixed, and twenty-five inches for revolving lights, their focal distance being four inches. These instruments, with a burner one inch diameter, and an initial power of eleven candles, condensed the light into a beam of 1304 and 2360 candles respectively. The power of a first order reflector light of sixteen reflectors, ranged on a frame having four faces, was equal to 9340 candles. These were the instruments (Fig. 1) which A. Fresnel,

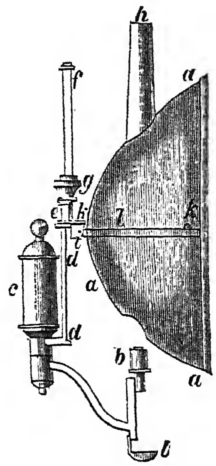

FIG. 1.

the celebrated physicist, replaced by optical apparatus of glass lenses and prisms acting by refraction and reflection in combination with a central lamp and multiple-wick burner of considerable power. In doing so he devised four optical agents: the annular lens, totally reflecting prisms, the cylindric refractor for small apparatus, and straight vertical reflecting prisms. These instruments he combined in different ways to form fixed and revolving apparatus suitable for lighthouse purposes. The annular lens subtended at the focus 45° vertically and horizontally, the focal distance being 920 m.m. (36·22 inches). Some of Fresnel's optical instruments in the hands of Mr. Alan Stevenson, underwent very notable alteration, extension, and improvement. The first order lens was extended to subtend 57° vertically, and reflecting prismatic rings were substituted below the lenses for silvered mirrors. The central portion of the first order fixed light apparatus (Fig. 2) was converted from a polygon formed of narrow lenses to a cylindrical drum, which drum was divided into sections having helical joints, and above and below the central belt reflecting prisms were introduced.

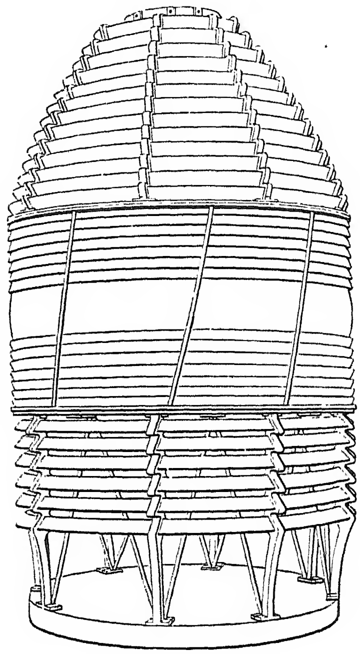

FIG. 2.

The next improvements were those of 1849–1850, by Mr. Thomas Stevenson, the main feature of which was that, for revolving lights, totally reflecting prisms generated round a horizontal axis were introduced above and below the lenses, lenticular action being thus extended throughout the whole height of the instrument (Fig. 3).

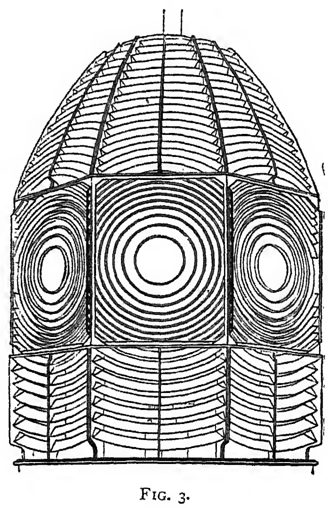

FIG. 3.

Then followed the dioptric spherical mirror, the dioptric holophote, the azimuthal condensing system, and its application to fixed, flashing, intermittent, and group flashing lights; the bivalve apparatus of 1859, which is really two holophotes ten feet in diameter, increased in power by a dioptric mirror, and numerous combinations of these and previously devised instruments.

One of the most notable of recent improvements is the hyper-radiant apparatus of 1330 m.m. or even greater radius, proposed by Messrs. Stevenson in 1869 (Fig. 4). This apparatus was designed to take advantage of the large and powerful flames of burners of greater diameter than five-wick; the introduction of burners of increased size having been inaugurated by Mr. Wigham in connection with his gas burners, and rendered possible, on financial grounds, with oil burners, by the introduction of paraffin. With revolving apparatus of 920 m.m. radius, it was clearly demonstrated that with burners of large diameter, much of the light, being exfocal, escaped condensation, and hence the hyper-radiant apparatus was designed to utilise and condense the rays proceeding from the large radiant. The light from one of the lenses of a hyper-radiant apparatus is more intense with the same size of burner in the focus than that from two lenses of 920 m.m. The hyper-radiant is now largely used by all lighthouse authorities. In 1872, Mr. Wigham suggested a very obvious method of increasing the power of a lighthouse by superposing in the lantern two, three, or four lenses, each with its own burner. Such arrangements have been introduced at several lighthouses, both in Ireland and England, but it is difficult to see what the advantage is, as it is quite easy with a single apparatus, properly designed, and single burner to get the same power and at a less cost. Mr. Charles A. Stevenson designed a form of refractor which is spherical in the horizontal and vertical planes, and this form was adopted in the apparatus of North Fair Isle lighthouse. The spherical refractor, if it has spherical profiles, loses in efficiency if carried beyond an angle subtending 20° at the focus, but when this design has combined with it Mr. C. A. Stevenson's equiangular prisms, as in the design for Sule Skerry lighthouse, there is less divergence, and hence less loss of light, than is the case with the Fresnel forms; in the case of the spherical lens, from the fact of its greater radius, and in the equiangular, from the prisms being of profiles of minimum divergence for exfocal light. In the design for Rattray Head apparatus, the equiangular prisms have been adopted to enable the lens to be carried to 80° of a vertical angle, the prisms at this high angle of refraction still remaining of good efficiency; whereas when lenses are carried to this high refracting angle by Fresnel's prisms, the lenses become very ineffective, owing to their great divergence for exfocal light. In recent designs by Messrs. Stevenson, of optical apparatus for New Zealand, lenses equiangular throughout have been introduced (Fig. 5).

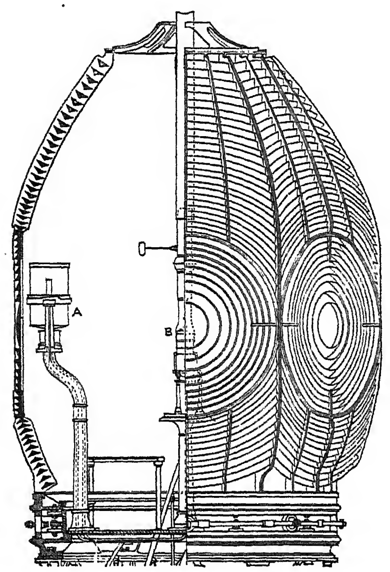

FIG. 4.

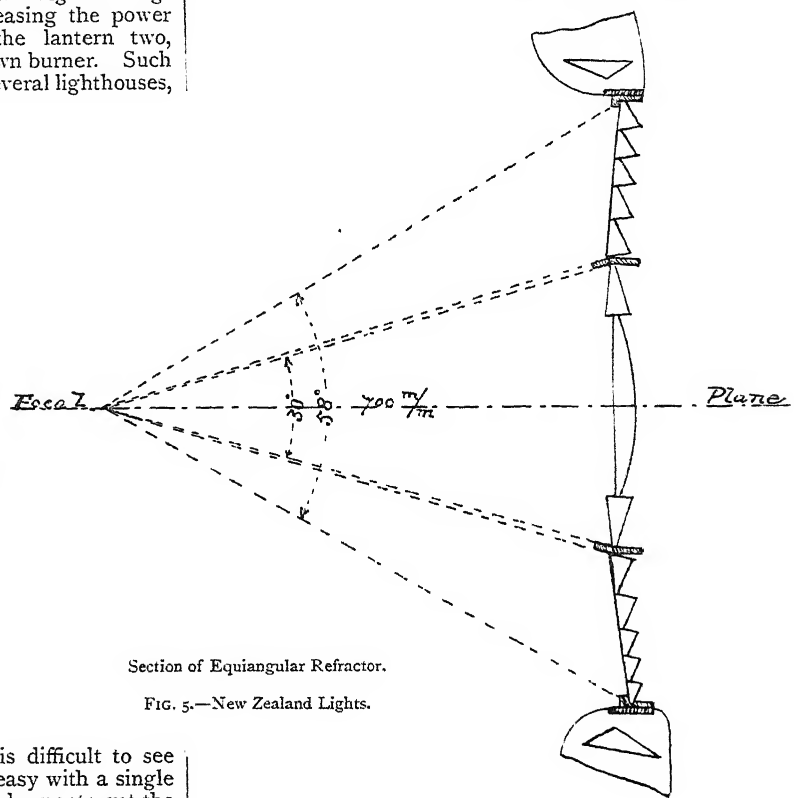


Section of Equiangular Refractor.

FIG. 5.—New Zealand Lights.

The increased and ever-increasing speed of steamships has necessitated the adoption, for over-sea and prominent lighthouses, of revolving, flashing, and group flashing apparatus, having short periods of light and darkness. This is desirable in order that the sailor may be able, in a short space of time, without appeal to a watch, to tell the character of the light he sees. But long before the days of fast steamers, Mr. R. Stevenson recognised the desirability of shortening the periods of light and darkness, and in 1825 he introduced the "flashing" distinction on the coast of Scotland, having periods of 5″ light and 5″ darkness. Subsequent experience has fully proved the utility of this striking characteristic. In 1874, Dr. Hopkinson proposed the important group flashing characteristic, which has since been largely adopted.

The length of the duration of a flash to be effective has been lately much discussed by lighthouse engineers and is a matter of great importance, for the shorter the flash can be made with efficiency, the stronger it can be made. Messrs. Stevenson have, in recent years, been gradually reducing the length of the flashes in apparatus designed by them, and in the case of the Isle of May electric light, installed in 1886, they reduced the flashes to half-second duration. They have not been followed in this by the lighthouse engineers of other countries, as, for example, in the case of St. Catherine's, lighted in 1888, where the flashes are 5″ duration. The French lighthouse engineers, however, have gone further, and within the last two years have designed lights, the duration of the flashes being only one-tenth second. This is going to the other extreme. M. Bourdelles and M. Blondel, in papers read before the International Maritime Congress, 1893, give the grounds on which they advocate such short flashes. They say, and say

truly, that physically even less than one-tenth second is sufficient to make the maximum impression on the eye, and conclude that a longer duration is therefore unnecessary. This would be a sound conclusion were the atmosphere always clear, but it is not so. Now it is physically true, as they admit, that the duration necessary for the full effect of a flash depends on the intensity of the light; a weaker flash must have a longer duration than a stronger one, to make the full effect on the retina. But by the time a powerful flash has pierced a few miles of hazy atmosphere, it is no longer powerful, and if it has not a duration suitable to its reduced power, it will not be seen so far. This is a question which cannot be settled on merely theoretical grounds, but must inevitably be a matter of experience. The following are a few figures showing the great power of some modern lighthouse apparatus now in use in the Trinity House and Northern Lighthouse Services, as compared with anything employed during the days of colza oil, fixed lights, and apparatus of many sides.

The Isle of May light has a calculated intensity of no less than 26,000,000 candles to each flash, while the St. Catherine's electric light, calculated on the same basis, has a strength of beam equal to 5,000,000 candles. The power of the La Heve electric light is stated at 23,000,000 candles.

Turning now to the ordinary lights, where paraffin oil is the illuminant, the following may be mentioned as being of very great power. The Bishop Rock, biform, with two eight-wick burners and hyper-radiant apparatus, gives a flash of 175,000 candles. The Eddystone, with two six-wick burners and first order apparatus, gives a flash of 75,000 candles. Sule Skerry, with one six-wick burner and hyper-radiant apparatus, gives a flash of 74,000 candles, and Fair Isle North, one six-wick burner and hyper-radiant apparatus, without upper and lower prisms, gives a flash of 72,000-candle power.

The result of recent improvements in the optical apparatus used in lighthouses, and in the increased power of the lamps, is that the mariner is now getting the benefit of lights of greater intensity and more characteristic appearance, easily and rapidly recognisable.

THE DEPARTMENT OF ENTOMOLOGY IN THE U.S. NATIONAL MUSEUM.

The staff of the Department of Insects of the U.S. National Museum has been reorganised, as a result of the death of the former Honorary Curator, Prof. C. V. Riley.

The reorganisation has been effected by the appointment of Mr. L. O. Howard, Entomologist of the U.S. Department of Agriculture, to the position of Honorary Curator of the Department of Insects; of Mr. Wm. H. Ashmead to the position of Custodian of Hymenoptera; and Mr. D. W. Coquillett to the position of Custodian of Diptera. All Museum custodians are honorary officers. Mr. M. L. Linell will remain as general assistant to the Honorary Curator.

The Department is at present in excellent working condition. It contains a very great amount of material in all orders, and in many unusual directions surpasses any collection in the United States. Among others, the following are of especial interest:—

(1) The large collection, in all orders, of the late Prof. C. V. Riley.

(2) All of the material gathered during the past eighteen years by correspondents, field agents, and the office staff of the Division of Entomology, U.S. Department of Agriculture.

(3) The greater part of the collection of the late Asa Fitch.

(4) The large collection, in all orders, of the late G W. Belfrage.

(5) The collections in Lepidoptera and Coleoptera made by Dr. John B. Smith down to 1889, together with the types of the Noctuidæ since described by Dr. Smith.

(6) The collection of Lepidoptera of the late O. Meske.

(7) The collection of Lepidoptera of G. Beyer.

(8) The collection of Coleoptera of M. L. Linell.

(9) The bulk of the collection, in all orders, of the late H. K. Morrison.

(10) The collection of Diptera of the late Edward Burgess.

(11) The type collection of Syrphidæ made by Dr. S. W. Williston.

(12) The collection of Ixodidæ of the late Dr. George Marx.

(13) The collection of Myriopoda of the late C. H. Bollman.

(14) Sets of the Neo-tropical collections of Herbert Smith.

(15) The collection of Hymenoptera of Wm. J. Fox.

(16) The collection of Tineina of Wm. Beutenmuller.

(17) The large Japanese collection, in all orders, of Dr. K. Mitsukuri.

(18) The African collections, in all orders, of Dr. W. S. Abbott, Wm. Astor Chanler, J. F. Brady, the last "Eclipse" expedition to West Africa, and of several missionaries.

(19) The large collection from South California of D. W. Coquillett, in Coleoptera, Hymenoptera, Lepidoptera and Orthoptera.

(20) The Townend Glover manuscripts and plates.

In addition to this material, there are minor collections which have been the result of the work of Government expeditions, or are gifts from United States Consuls and many private individuals.

This enormous mass of material is being cared for by the active and honorary force of the Department, and the perpetuity of the collection is assured. The National Museum building is fireproof, and this, together with the fact that it is a National institution, renders the Department of Insects, perhaps, the best place in the United States for the permanent deposit of types by working specialists in entomology, and for the ultimate resting-place of large collections made by individuals.

The policy of the Museum at large, with regard to the use of its collections by students, is a broad and liberal one. Students are welcome in all departments, and every facility is given to systematists of recognised standing.

NOTES.

It is proposed by the Administrative Council of the Pasteur Institute to make an international appeal for subscriptions to erect a monument to the memory of Pasteur.

An ordinary meeting of the Royal Society, for the reading of papers though not announced upon the printed list of arranged meetings, will be held on the 28th inst.

Sir Archibald Geikie and Prof. Story Maskelyne have been elected corresponding members of the Munich Academy of Sciences, in the Mathematical and Physical Section; and Dr. H. B. Swete, of Cambridge, has been elected a corresponding member in the Philosophical and Philological Section of the same Academy.

In accordance with the arrangement mentioned in our last week's issue, Dr. A. G. Butler becomes Senior Assistant-Keeper of the Zoological Department of the British Museum, with special charge of the section of insects, and Mr. Edgar A. Smith and Dr. R. Bowdler Sharpe have been promoted to fill the two other assistant-keeperships. Mr. Vernon Herbert Blackman, of St. John's College, Cambridge, has been appointed, after competitive examination, an assistant in the Department of Botany, in the place rendered vacant by the promotions consequent upon the retirement of Mr. Carruthers.

WITH reference to the aurora briefly noted in our last number (p. 35), Mr. J. Shaw writes from Tynron, Dumfriesshire, as follows:—"At 11 p.m. November 9, I saw an aurora extending from the north-west to the north-east, where it began to break into long lines, one line lying above the planet Jupiter. It occupied about one-fourth of the distance from horizon to zenith at its widest. The luminosity was singularly free of tremulous motion, and between it and the spectator were ragged patches of black clouds, such as often portend rain, which began to fall in torrents four hours later."

FOR some years the need has been felt at the Harvard College Observatory, of some means of making a more prompt announcement of the results of its work. It is proposed therefore to issue a series of circulars, as required, to announce any matters of interest, such as discoveries made there, the results of recent observations, new plans of work, and gifts or bequests. It is not proposed to give these circulars a wide distribution, but rather to use them as a means of bringing new facts to the attention of the editors of astronomical and other periodicals, and thus secure the immediate publication of such portions as would be of interest to the readers of these periodicals. The distributions will be made without charge to such persons as will be likely to use the results.

IN view of the unsatisfactory condition of veterinary anatomical nomenclature, we are glad to learn from the *Lancet* that the section of the recent sixth international veterinary congress detailed to give an opinion as to the necessary steps to be taken to remedy it, reported that the *Nomina Anatomica* of His be recognised as a basis for an international Latin nomenclature of veterinary anatomy, and that the work of adaptation, as well as the creation of new Latin denominations, should be allotted to certain anatomists of the countries represented, with the right of co-optation. This recommendation was unanimously adopted, and the following gentlemen were appointed to undertake this task, MM. Müller of Berlin, Arloing of Lyons, Lorge of Brussels, Sussdorf of Stuttgart, Schmalz of Berlin, Martin of Zürich, Rubeli of Bern, and Szakall of Pesth.

THE Manchester Museum was opened to the public last Sunday afternoon. The attendance was considered satisfactory, some five hundred visitors entering. Attention was pretty evenly distributed through the various departments, but a special attraction was the collection of Egyptian antiquities, recently added to the museum, and consisting of palettes for grinding metal tools, ceremonial and other flints, mace-heads, pottery (figured, polished, and rough), stone vases, art jars, &c. Objects arranged naturally, as specimens of the Porifera, also found favour. Arrangements are being made for demonstrations to be given upon the various classes of exhibits; and it is expected that this concession, rendered possible by the important pecuniary assistance from the Manchester Corporation, will be fully appreciated.

THE Executive Committee appointed to make the necessary local arrangements for the reception of the British Association in Liverpool, next year, held a meeting on Friday last, under the presidency of Sir Wm. Forwood. Among those present were the secretaries, Prof. Herdman, F.R.S., and Messrs. Isaac Thompson and Willink; the honorary treasurers, Mr. Reginald Bushell and Mr. C. Booth, jun.; Prof. O. Lodge, Drs. Hope and Forbes, and others. It was announced that the following gentlemen had been elected by the Council of the Association vice-presidents of the meeting, to be held from Wednesday, September 16, to September 23, 1896: The Lord Mayor (the Earl of Derby, K.G.), Lord Sefton, Sir W. B. Forwood, Mr. M. Rathbone, Mr. George Holt, Mr. T. H. Ismay, Principal Rendall, Sir Henry Roscoe, and Mr. W. Crookes. The President-elect is Sir Joseph Lister, Bart., F.R.S. A sub-committee was appointed to superintend the hospitable arrangements, which will be conducted on a liberal scale, and it was proposed to arrange for an excursion to the Isle of Man at the conclusion of the meeting. This excursion would occupy several days, and it was hoped that a local committee in the island would be appointed and facilitate arrangements. The honorary treasurers reported that they had received a large number of subscriptions; but as they had no reason to consider the list complete, they proposed to defer the publication of the list.

THE vagueness of the English names of our wild plants is one of the stumbling-blocks in the way of the student of botany. Those given in our text-books are, for the greater part, mere book-names—often simply translations of the Latin names—which are not, and never have been, applied to the plant in any part of the country. Even with regard to familiar names in common use, many—as for instance, eyebright and harebell—are used for quite different plants in different parts of the country. On the continent, and especially in Germany, where the more educated peasantry have a much better knowledge of wild flowers than is the case with our agricultural labourers, the state of things is still worse. In his *Internationales Wörterbuch der Pflanzennamen*, Ulrich gives, in many cases, from twelve to twenty German names for the same species; and it is stated that for some species there are more than one hundred names in use. We learn from *Die Natur* that an attempt is being made to correct this evil. The *Allgemeine Deutsche Sprachverein* of Berlin offers two prizes, of the value of six hundred and four hundred marks, respectively, for the best schemes for a uniform German nomenclature of plants for schools. It would be an immense gain to the teaching of botany in schools if something of the same kind could be done in this country. Could not the *Journal of Botany* or the Botanical Exchange Club take it up?

AFTER a part of last week's issue of NATURE had been printed off, containing a note announcing the death of Dr. George Dawson, we were rejoiced to be able to stop the press and cancel it, as a cablegram contradicted the rumour.

THE death is announced of M. A. M. Villon, the author of the "Dictionnaire de chimie industrielle" and other important works connected with chemical industry. He was only twenty-eight years of age.

AN International Marine and Fisheries Exhibition will be held at Kiel next year, in connection with a provincial exhibition for Schleswig-Holstein, and will be open from May 13 to the end of September.

THE earthquake which occurred at Rome on the first day of this month, and was noted in these columns (p. 12), was preceded by severe shocks, felt in parts of the United States, in the early morning of October 31. The shocks appear to have especially affected Ohio, Illinois, and Indiana.

ANOTHER important atmospheric disturbance approached our western coasts from the Atlantic on Friday last, 15th instant, causing further south-westerly gales and considerable damage; and before this disturbance had passed away a secondary depression reached St. George's Channel, on the following day. The rainfall which accompanied these storms was very considerable, amounting to nearly three inches in two days at Holyhead. In the storm of Saturday, the Bishop's lighthouse, off Pembroke, was struck by lightning.

THE Committee formed for the purpose of erecting a memorial to the late Dr. Valentine Ball, C.B., F.R.S., Director of the Science and Art Museum, Dublin, announce their desire to close the subscription list at an early date, and trust intending sub-

scribers will soon send their donations to the Treasurer, Dr. Samuel Gordon, Hume Street, Dublin. The subscription to the memorial is limited to one guinea. It is proposed to place a marble bust of Dr. Ball in the National Museum, the scene of his latest labours. It is further proposed, should there be sufficient funds, to have a portrait of Dr. Ball painted and placed in a position to be hereafter determined. About £120 has so far been subscribed.

THE first meeting of the one hundred and forty-second session of the Society of Arts was held on Wednesday evening, November 20. Previous to Christmas there will be four other ordinary meetings, as follows: November 27, locomotive carriages for common roads, by Mr. H. H. Cunynghame; December 4, on mural painting, with the aid of metallic oxides and soluble silicates, by Mrs. Anna Lea-Merritt and Prof. W. C. Roberts-Austen, C.B., F.R.S.; December 11, water purification by means of iron, by Mr. F. A. Anderson; December 18, machines for composing letter-press printing surfaces, by Mr. John Southward. The following papers will be read at meetings after Christmas: Dairy produce, by Mr. George Barham; the making of a great University for London, by Prof. Silvanus P. Thompson, F.R.S.; some native Irish industries, by Prof. Haddon; standards of light, by Mr. W. J. Dibden; ortho-chromatic photography, by Captain W. de W. Abney, C.B., F.R.S.; the garden in relation to the house, by Mr. F. Inigo Thomas; English book illustrations, 1860-70, by Mr. Joseph Pennell; Punjab irrigation, ancient and modern, by Sir James Broadwood Lyall, K.C.S.I.; the economic development of Kashmir, by Mr. Walter R. Lawrence. The following courses of Cantor lectures have been arranged: W. Worby Beaumont, on mechanical road carriages; Dr. J. A. Fleming, F.R.S., on alternate current transformers; Prof. J. M. Thomson, on the chemistry of metals and alloys employed for building and decorative purposes; Mr. H. Graham Harris, on refrigeration; Mr. Henry A. Miers, on precious stones; Mr. James Swinburne, on applied electro-chemistry. Two lectures, suitable for a juvenile audience, will be delivered on Wednesday evenings, January 1 and 8, 1896, by Prof. John Milne, F.R.S., on earthquakes, earth movements, and volcanoes.

A CONFERENCE, presided over by Sir Courtenay Boyle, and largely attended by representatives of municipal corporations, public companies, and others interested in the supply of electricity, was opened in the Westminster Town Hall yesterday, to consider the revised regulations made by the Board of Trade under the Electric Lighting Acts of 1882 and 1888. We summarise the report in the *Times*. The regulations were discussed seriatim, and a number of important changes were accepted. With reference to the Board of Trade definition of electrical pressure, Prof. Ayrton, who, with Mr. Compton, represented the Institution of Electrical Engineers, proposed that the expression "pressure" should mean "the difference of electrical potential between any part of any conductor and the earth, or between any two adjacent wires on the three or five-wire system." The Chairman promised that the proposal should receive careful consideration. He added, that he intended to advise the Board of Trade to raise the alternating current limit from 100 volts to a higher figure, say to 220 volts, or thereabouts. With regard to the low-pressure continuous current limit, he thought that it might be raised slightly above 300 volts. Discussion took place upon the regulation that "no high-pressure electric line shall be used for the transmission of more than 200,000 watts, and Mr. Compton suggested that the limit should be 500,000 watts." The Chairman said he intended to advise the Board of Trade not to adhere to the limit of 200,000 watts, but he thought that of 500,000 watts a little too high. He offered to make an important amendment in the clause referring to tests of insulation, the clause in its amended form reading: "Every electric main shall be tested for insulation after having been placed in position, the testing pressure being at least 200 volts, and the undertakers shall duly record the results of the tests of each line or section of a main." With reference to the clause requiring a test of insulation before a high-pressure circuit can be brought into use, the Chairman suggested the introduction of words providing that the test required in the case of electric lines should be twice the pressure to which the lines were to be subjected in use, and in the case of machines or apparatus intended to form part of a high-pressure circuit 50 per cent. more. As to the question of leakages from gas mains, and the accumulation of explosive mixtures in electrical conduits and street boxes, the Chairman said he would be prepared to recommend the Board of Trade to accept a clause based on that suggested by the Institution of Electrical Engineers, that is to say, imposing upon undertakers the obligation to take reasonable means to prevent the influx and accumulation of gas in boxes, and to give notice to the gas companies whenever an accumulation of gas therein was discovered. He accepted that clause on the understanding that there must be some further regulation with regard to the ventilation of street boxes.

A NOTE on the tinfoil grating as a detector for electric waves, by T. Mizuno, appears in the *Journal* of the College of Science of Tokyo. The author has been repeating and extending Aschkinass' most interesting experiments on this subject. The gratings employed are formed by coating a flat wooden block with tinfoil, and then cutting on it a number of fine parallel slits with a sharp knife. Two gratings have been used, one having a resistance of 130 ohms, and the other of 232 ohms. The wave-length of the electric radiation employed was about 60 cm. On exposure of these gratings to the electric radiation, the resistance fell in some cases as much as 11 ohms and 42 ohms respectively. Gentle tapping was sufficient to cause the resistance to increase to almost its former value. The experiments indicate that the angle which the plane of polarisation of the radiation makes with the strips of the grating influences the results to a certain extent, a greater decrease of resistance taking place when the strips are perpendicular to the plane in which the primary oscillations take place. The author has made some experiments with a view of determining whether the change in resistance is due to a molecular change in the tinfoil, or whether the change is a mechanical one. He has constructed gratings in which the spaces between the strips were much larger than in the above gratings. With this grating, however, no indication of a decrease of resistance under the action of electric radiation was observable. Gratings formed of fine german-silver wire and fine iron wire, also, showed no effect. The author concludes that the change is a mechanical one, and suggests that it may be due to small jagged points on the neighbouring strips coming into contact under the influence of the electric waves.

THE competition for mechanical carriages, which was arranged by the *Times-Herald* of Chicago to take place on November 1, has been postponed until the 28th inst., at the request of a number of the competitors who had entered for the competition, but were not prepared. According to the *Journal* of the Society of Arts, the *Times-Herald* thereupon offered a prize of £100, to be divided amongst those competitors who went over the course arranged for the race. This course extends over the line of boulevards which surround Chicago to a place named Waukegan on the lake shore, thirty miles to the north of the city. Several vehicles started, but only one completed the course—the carriage entered by A. Mueller, of Decatur, Illinois. The vehicle carries four persons, and is driven by a gasoline motor. The total distance covered was ninety-two miles, and the time taken 8 hours 44 minutes.

IF the Buchan Field Club succeeds in carrying out the ethnological survey sketched in its *Transactions* (1895) by Mr. T. Gray, who gives also the results of preliminary observations made by Mr. J. F. Tocher and himself, it will not only fill an important hiatus in the ethnographic chart of Great Britain, but also set an example which may be followed with advantage by similar societies all over the country. The observations referred to were made at the annual Buchan gathering, held this year at Mintlaw, and though no definite conclusions can be safely made from them, they show that a continuation of the survey will lead to interesting results, and help to settle a number of vexed questions in ethnology and history. The class of people at such gatherings as that at which the measures were made is very typical of the natives of the district, and the statistics obtained by Mr. Gray, and those working with him, should be of great value in determining the accurate anatomy of the typical native of Buchan.

A VALUABLE contribution to the existing literature of water-bacteriology has been recently made by M. N. van der Sleen. This monograph is a record of bacteriological investigations made during more than four years on the Amsterdam water-supply. The author has identified and described no less than 80 varieties of water microbes, some of which he regards as new, whilst others are identical with those already discovered by other investigators. A most helpful diagnostic aid is furnished by the 118 excellent photographic figures of microbes which accompany the text. No cholera bacilli were at any time found, and only one form which at all resembled them, although a careful search was made at a period when cholera had broken out in the vicinity of the intake of the water-supply, and when the river Vecht was declared contaminated by the authorities. M. van der Sleen has endeavoured to give water-bacteriologists fresh assistance in the difficult task of recognising the bacteria found in water, and the conscientious care with which he has accomplished this tedious piece of work eserves the highest praise.

THE well-known difficulty of obtaining instruments which will indicate rapid variations of temperature, has induced Mr. Paul Czermak, of Graz, to try thermo-elements with very fine wires for meteorological observations. These are better than thermometers with platinum bulbs, and much superior to glass-bulb thermometers, where rapid variations are to be measured. One of the instruments constructed consists of a thermo-couple of copper and constantane wire 0·1 m.m. thick. The ends are soldered to two hollow copper cylinders drawn into a point at the ends, and mounted side by side on a wooden support. The cylinders contain water, and hold ordinary thermometers indicating the average temperature. This instrument, when used in circuit with a strongly-damped aperiodic galvanometer, showed variations amounting to 2° C. within five minutes on a clear frosty Tirolese morning. The stratification of the air in layers of different temperatures was less in the afternoon. The paper describing these results, in *Wiedemann's Annalen*, also gives an account of a "relative actinometer" consisting of two concentric copper cylinders. The interior one is empty, and across one end of it are placed three thermo-couples in parallel, protected from draughts by a plate of rock-salt mounted obliquely to the axis of the cylinders. This instrument indicates the slightest variations of the intensity of solar radiation, such as those produced by different thicknesses of a filmy cloud.

SIR ROBERT BELL is said to have discovered a very large river flowing into James Bay. The river rises near the upper waters of the Ottawa, and drains a large area hitherto unexplored. The volume of water is so great as to make the river rank among the largest in Canada. It is navigable through the greater part of its course, but about one hundred miles from its mouth the descent becomes greater, and a series of rapids are formed. The name "Bell River" is proposed, in honour of its discoverer.

WE are indebted to the Vienna correspondent of the *Times* for the following information. At the beginning of this month the German Society for Geographical Discovery, and the special committee which has been organised for the purpose of promoting the exploration of the South Polar regions, held a joint sitting in Berlin, which Herr Julius von Payer, the well-known Austrian Arctic traveller, was requested to attend. In the course of the proceedings he was invited to modify the arrangements he had himself made in connection with the expedition to North-East Greenland, and, if possible, to co-operate with the Germans in undertaking an expedition to the South Pole. Herr von Payer replied that, although he was not adverse to the proposal, he could make no definite statement until he had ascertained the opinion of the Vienna committee, who had in hand the arrangements relative to the intended Austro-Hungarian expedition to Greenland. Within the next few days the Vienna committee will meet, under the presidency of Count Wilczek, with the object of considering the German proposals. The invitation to act in concert with Germany seems to be regarded with favour in Vienna. Herr von Payer has stated that, in view of the multitude of scientific and artistic opportunities afforded by a visit to Antarctic regions, he would have no objection to alter the destination of the contemplated Austro-Hungarian expedition. During the preliminary discussion, which took place in Berlin, it was decided that the expedition should consist of two steamers equipped on the most improved lines. The first landing would be effected on Kerguelen Island, whence it would be possible to proceed in two different directions—namely, either south or south-west, leading to a totally unknown region, or south-east towards the Magnetic Pole, in which direction a continent is supposed to exist. Geographical discovery, of course, would be the chief object of the expedition, but equally valuable results are expected to accrue to botany, zoology, and geology. About eighteen months would be required to prepare and organise the expedition, and the cost is estimated at about 1,000,000 marks. In order to achieve success the expedition would remain absent from two and a half to three years, it being considered essential that at least two winters should be spent in the Antarctic regions.

THE seventh number of the current volume of the *Verhandlungen der Gessellschaft für Erdkunde zu Berlin* contains a discussion, by Hermann Moedebeck, of the project of reaching the North Pole by balloon, with the conclusion that, in our present ignorance of Arctic wind currents, it is impossssible to decide as to the probabilities of success. Dr. Hedin continues an account of his journey across the Takla-Makan desert east of Yarkand. Wegener gives a summary of the papers read at the Geographical Congress in London. The volume refers to the departure of an expedition, under Humpelmayr and Sperhinger, from the Somal coast, in order to march southwards across the Galla country to Mombasa. The more important contributions offered to this Society are published in its *Zeitschrift*, of which we have received the fourth part of vol. xxx. This contains the third part of the report by the cousins Sarasin upon their travels in Celebes, describing the journey, in the winter of 1894, across the centre of the island from Boni to the Gulf of Tomini. The report is mainly narrative, but contains many notes on the zoology, anthropology, and geology of the district traversed. The monographs previously issued by the Sarasins, containing zoological and anthropological discoveries made during their visit to Ceylon, are well known, and encourage us to expect important results from their present journey.

THE principal article in the last number of the *Mittheilungen* of the Geographical Society of Vienna (Bd. xxxviii. Nos. 7 and 8) is a memoir, by R. Payer, on the districts of Eastern

Peru included in the Amazon basin. It consists mainly of an account of the various diseases. Dr. Gavazzi gives a short account of the hydrology of the lower part of the River Krka in Dalmatia. Among the smaller articles contributed is a biography of Huxley by Dr. Haas, an account of the German expedition of Lieut. von Carnap-Querheimb and Dr. Grüner in Togoland, and of Dr. Krüger up the Palena river in Chile. There is also a short notice of Glave, who did excellent work under Stanley on the Congo, and died there in May last. It also contains a report on the various expeditions engaged in work in Africa. From this we learn that Capt. Bottego is attempting to march from Barawa, on the Somali coast, to Logh, on the Juba; thence he is to cross to Lake Rudolf, and explore the course of the Omo, from its mouth to the point where Prince Ruspoli was killed. The King of Italy and the Italian Government have each contributed 40,000 lire for this expedition. Prince Boris, the well-known Russian sportsman, has been shooting in the Ogaden country in Somaliland, and has traced the Dachato river to its confluence with the Webi Schebeyli. Dr. Humpelmayr left Berbera in June in order to march across East Africa from north to south, as far as Mombasa.

THE Zoological Society have just issued the thirty-first volume of the *Zoological Record*, containing a summary of the zoological literature published in the year 1894. The various articles have been prepared by Messrs. J. A. Thomson, R. Lydekker, R. Bowdler Sharpe, G. A. Boulanger, W. A. Herdman, B. B. Woodward, D. Sharp, F. A. Bather, R. Hanitsch, and Miss Florence Buchanan. The whole volume has been edited by Dr. D. Sharp, F.R.S., of the Cambridge University Museum. Great credit is due to the Society and to the Editor for the early date at which this volume has been published. We observe that the corresponding *Record*, just finished in Wiegmann's *Archiv*, only relates to the year 1890, being thus *four years* behind that of its English rival. A very useful feature in the present volume is the newly revised list of abbreviations used in the *Record* for the titles of the *Journals* and *Transactions* that contain zoological papers. These periodicals are now, as is well known, exceedingly numerous, and increase in number every year. Some sixty or seventy new titles have been added to the present edition. The principal libraries in London and Cambridge, in which the various periodicals are to be found, are indicated by key-letters attached to each title, so that the recorder in each subject may always know where to go for his information. We observe that the present volume contains no records for the Crustacea, Arachnida, Myriopoda, and Cœlenterata, the naturalists to whom these subjects were assigned (Mr. R. I. Pocock and Dr. S. J. Hickson) not having delivered their manuscripts at the promised date. These deficiencies are much to be regretted; but the early appearance of a *Zoological Record* is a matter of so much importance, that we cannot but approve of the Editor refusing to wait for the convenience of his tardy coadjutors.

A FLORA of the Gramineæ of France, Belgium, and Switzerland is in preparation by M. T. Husnot, of Cahan, near Athis (Orne).

THE Christmas course of lectures, adapted to a juvenile auditory, at the Royal Institution, will be delivered this year by Prof. John Gray McKendrick, F.R.S. The subject will be "Sound, Hearing, and Speech," and the lectures will be experimentally illustrated.

A SKETCH of the life and personality of M. Berthelot, now Minister of Foreign Affairs, appears in the current number of the *Chemist and Druggist*. "The Republic has no use for chemists," is said to have been the remark made by the tribunal which condemned Lavoisier to the guillotine. The words are probably apocryphal, but, at any rate during this century, France has in many ways shown her appreciation of the abilities and work not only of chemists, but of all her scientific investigators.

IN our report of the opening of the Chingford Museum (p. 16), the writer inadvertently wrote "Dengey Hundred" in reference to Mr. Walter Crouch's collection of shells. He desires us to state that the collection was made in the Becontree Hundred, which comprises the Forest District.

THE Central Hydrographic Office of Vienna has published its first *Jahrbuch* containing daily or monthy rainfall values at 861 stations, and tidal observations at 493 stations, for the year 1893. The work occupies 562 large folio pages, and contains brief discussions of the observations, arranged according to the various river systems, and a map showing the yearly distribution of rainfall over the entire area. The publication is a valuable contribution to meteorological and hydrographical science.

THE additions to the Zoological Society's Gardens during the past week include a Blotched Genet (*Genetta tigrina*), two Crossed Snakes (*Psammophis crucifer*), a Smooth-bellied Snake (*Homalosoma lutrix*), a Rough-keeled Snake (*Dasypeltis scabra*), a Many-spotted Snake (*Coronella multimaculata*), a Hygian Snake (*Elaps hygiæ*) from South Africa, presented by Mr. J. E. Matcham; eight Great Tits (*Parus major*), British, presented by Mr. Brunsden; a Puffin (*Fratercula arctica*), British, presented by Dr. J. B. Johnson; two Lions (*Felis leo*, ♂ ♀) from Africa, deposited; a Black-faced Spider Monkey (*Ateles ater*) from Eastern Peru, purchased.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—A telegram, received from Kiel on November 18, announces the discovery of a new comet by Mr. Perrine at the Lick Observatory on the 16th inst. At the time of observation the comet was in R.A. 13h. 44m. and Decl. 1° 40′ N.; accordingly, it was nearly midway between ζ and τ Virginis, and would rise at London about 3.40 a.m. It is described as having a bright tail.

THE NEW MEROPE NEBULA.—The round bright nebula very close to Merope, in the Pleiades, which was discovered by Prof. Barnard in 1890, has recently been observed by him with special reference to its position (*Ast. Nach.* 3315, p. 42). With respect to Merope, its position angle for 1895·67 was 166°·6, and distance 33″·58; these figures agree remarkably well with the earlier measurements, and they indicate that the place of the nebula can be determined with such precision, that repeated observations may be expected to show whether it has any proper motion, or physical connection with the star. It is remarked that the nebula is only difficult in small telescopes because of its extreme closeness to the star, and that away from the star it would be an easy object in almost any telescope. The use of an occulting bar in the eyepiece of the telescope would probably facilitate observations of the nebula.

NUMBER OF NEBULÆ.—The number of known nebulæ has during the past few years been so largely increased by the labours of different observers, and the modes of publication have been so varied, that Dr. Dreyer's new index catalogue of the recent discoveries will be highly appreciated (*Mem. Roy. Ast. Soc.* vol. li. p. 185). This is a continuation of the well-known "New General Catalogue," which contained particulars of the 7840 nebulæ and clusters known up to the end of 1887, and brings the information to the beginning of the present year. The seven years' observations have resulted in the detection of 1529 new nebulæ, so that the general catalogue and the index together give the positions and descriptions of 9369 objects. More than half of the new discoveries are to be placed to the credit of M. Javelle, who has the advantage of employing the great refractor of the Nice Observatory. It is notable that only a very small proportion of new nebulæ has been discovered by the photographic method. Most of the objects included in the index are very small and faint, and it is remarked that they are probably only a small fraction of the total number visible in large telescopes. Dr. Dreyer considers it desirable that some of the possessors of large telescopes should turn their attention from the search for very faint nebulæ to "the less showy but more useful work of verifying the many old nebulæ which require re-observation."

A NEW STAR IN THE CONSTELLATION CARINA.—The first number of the Harvard College Observatory *Circular* contains a note to the effect that, from an examination of spectrum-photographs taken at the Arequipa Station of the Observatory, Mrs. Fleming has discovered that a new star appeared in the southern constellation Carina in the spring of this year. A photograph of a number of stars in the constellation contained a spectrum having bright hydrogen lines accompanied by dark ones of slightly shorter wave-length. Upon comparing this spectrum with those of Nova Aurigæ and Nova Normæ, it was seen that all three resembled one another, and were apparently identical in their essential features. A later photograph showed a slight change in the spectrum; a line at about wave-length 4700 being as bright as the hydrogen lines, though on the earlier photograph it was barely visible. These facts led to a close examination of all the sixty-two photographs of the region containing the star. Upon the first, taken in May 1889, no trace of the star could be made out, though stars of the fourteenth magnitude had recorded their existence. The star first appears on a negative taken on April 8 of this year, and last upon one obtained on July 1, its magnitude during the intervening period having diminished from the eighth to the eleventh. The approximate position of the star is R.A. 11h. 3·9m., Decl. − 61° 24′.

CHOLERA IN GERMANY IN 1894.

THE part just issued of the *Arbeiten aus dem Kaiserlichen Gesundheitsamte* is devoted to a very elaborate report on all the cases of cholera which occurred in Germany during the past year. The inquiry has been so arranged that each district is responsible for its own report. Thus Prof. Dr. von Esmarch has drawn up the document relating to East Prussia, Prof. Dr. Flügge furnishes the statement for Schlesien, Prof. Dr. E. Fraenkel describes the outbreak which took place in the neighbourhood of Marburg, and so on, whilst a general introduction has been written by Regierungsrath Dr. Kübler.

In all 1004 cases of cholera occurred between May 23 and the middle of December, 1894, out of which 490 ended fatally. These figures, taking the population of the Empire at its official estimate of 49,429,470, represent 0·2 cases of cholera per 10,000, and a mortality from cholera equal to 0·1 per 10,000. The report is extensively illustrated, but one of the most instructive appendages is a map giving a graphic representation of localities in which cholera was notified. Here at a glance it may be seen how Germany suffers in this respect from her close proximity to Russia and Galicia in the eastern portions of her Empire, by far the greater number of outbreaks having taken place in East and West Prussia, whilst in the districts bordering on France, Belgium and Holland, hardly any cases of cholera occurred.

Dr. Kübler des not hesitate to assert that practically all the cases of cholera which took place were attributable to fresh infection imported into the country. West Prussia was last year at a particular disadvantage in this respect, for whilst cholera has invariably found its way from Russia along the water-ways, this part of Germany, being so intimately connected with Russia by the Vistula, in 1894 a specially alarming outbreak of cholera raged in these Russian and Galician districts, and thus every opportunity was afforded for its ingress into Germany.

The various reports seem to be almost unanimous in stating that cholera is disseminated throughout the Empire well-nigh exclusively by means of the traffic along the rivers or water-ways of the country, and that it is here that the greatest watchfulness has to be exercised. Such surveillance has, however, exerted a most salutary influence upon the hygienic conditions obtaining on ships, and although the interference was in the first instance opposed by the men, the latter are now most eager and active in carrying out the sanitary improvements, and the best results have ensued.

It is interesting to note that not a single case of cholera occurred in Hamburg,[1] and only six in the whole of the Elbe district.

There cannot be a doubt that these most satisfactory results are a direct consequence of the splendid way in which the regulations drawn up by the German Cholera Commission of 1893 were carried out, and that it is to the conscientious manner in which the various officials fulfilled their instructions, that Germany owes her comparative freedom from cholera and its restriction when an outbreak did occur.

[1] The fatal case of cholera, which occurred in the Hamburg Hygienic Institute, is not included, as this was due to accidental infection during the carrying out of some laboratory experiments on cholera.

Prof. Flügge cites an interesting table confirming the improvement which has taken place in combating cholera, in which the total number of cases of cholera which have occurred in Oberschlesien from the years 1831 to 1894 are given.

Year.	Cholera cases.	Year.	Cholera cases.
1831	1658	1855–56 ...	5498
1832	3270	1866	9069
1836	4324	1867	4438
1837	1159	1872–73 ...	2332
1848–49 ...	5903	1874	2499
1851	898	1893	7
1852–53 ...	3856	1894	346

This improved condition, which is so apparent within the past twenty years, Prof. Flügge ascribes to the achievements of Robert Koch, whose labours have revealed not only the nature of cholera, but also the most effective way of dealing with it and crippling its power.

But perhaps the most striking testimony to the effectiveness of the measures taken to stamp out cholera, is to be found in the fact that in spite of the prevalence of cholera in East and West Prussia, the army manœuvres were conducted on a large scale in this district, and no cases of cholera occurred amongst the troops. As an instance of the precautions taken, it may be interesting to read the following instructions which were issued, such instructions being by no means the most elaborate which were carried into execution.

During the mobilisation of troops on the Vistula, no eatables were allowed to be taken; to prevent the river water from being drunk, casks of boiled drinking water accompanied the soldiers, and every man was provided with an infusion of tea; further, it was ordered, and most strictly carried out, that all articles of clothing which had come in contact with Vistula water, were not to be returned to the barracks, but to be sent straight to the disinfecting station, and the men were further obliged to wash their hands with soap and pure spring water on the parade ground each time after the various drills had been gone through.

There seems to be no doubt that personal disposition to cholera, as in diphtheria and other zymotic diseases, varies with the individual, and members of a cholera-stricken household, although not themselves affected, may in cholera, as also in diphtheria, become the transmitters of the disease. This is an accepted fact in Germany, and Dr. Kübler states that last year this received fresh confirmation from the bacteriological evidence afforded by numerous investigations of perfectly healthy persons in cholera surroundings. The isolation of these suspects, Dr. Kübler regards as an important measure in helping to restrict cholera-infected areas.

This disposition to cholera, even in cholera-disposed individuals, appears to vary at different seasons of the year, and the consensus of opinion, derived from all parts of Europe, decrees the late summer and autumn as the period when the chances of infection are greatest. What the special circumstances are which determine this seasonable predisposition, no one rightly understands, and a great diversity of opinion on this question exists; but there can be no doubt as to the facts, and the following statistics of cholera cases per month, collected over a period of more than thirty years in Schlesien, bring out this point very clearly.

January ...	743	July ...	2029
February ...	515	August ...	7065
March ...	381	September ...	11065
April ...	591	October ...	10787
May ...	712	November ...	6949
June ...	1446	December ...	2648

The organisation and elaborate machinery necessary to combat effectively with cholera, and the discipline with which the sanitary precautions have been carried out in Germany, call for ungrudging admiration; it is, therefore, with the more surprise that we learn from Prof. Flügge's report how much remains yet to be accomplished in the management of so important a matter as disinfection. The most approved apparatus was frequently rendered useless by the ignorance of those to whom the work of disinfection was entrusted. "The modern practice and technique of disinfection is something," writes Prof. Flügge, "which every doctor does not *eo ipso* understand or can learn either from

books: it requires, of necessity, a thorough theoretical and practical training. The control of disinfection is in the majority of cases left in the hands of police officials who have no knowledge of the subject whatever, and thus numerous mistakes are made, and much unnecessary damage to property ensues. . . For cholera-disinfection, in my opinion, special courses of instruction should be provided for disinfectors in both the theoretical and practical application of the subject."

We cordially commend the perusal of this valuable report to our own public authorities, who might, thereby, possibly be stimulated to take some serious and effective steps in staying the ravages of, to us, a far more deadly enemy, *i.e.* diphtheria. The Hamburg cholera disaster has not been without its lesson to Germany; surely we need wait no longer for our authorities to be similarly roused to successfully combat diphtheria.

G. C. FRANKLAND.

A JAMAICA DRIFT-FRUIT.

THE dispersal of plants by oceanic currents is a subject full of interest, and no apology is needed in bringing it forward if thereby we stimulate those who have opportunities for observing the effects of this agency in various parts of the world. The valuable contribution made to the literature of the subject by Mr. W. B. Hemsley, F.R.S., in the "Botany of the *Challenger*," and since added to by himself, Mr. Guppy, and others, cannot fail to enlarge our knowledge in regard to the origin of plant-life on oceanic islands as well as on the littoral of much larger areas. Our first acquaintance with the fruit of the remarkable *Lodoicea* of the Seychelles, for instance, was as a waif floating on the surface of the sea, and hence one of its familiar names *Coco-de-mer*. In the West Indies the ripe fruits of a palm unknown in the Greater Antilles are continually brought by the Gulf Stream from the south, and washed ashore at Jamaica and other places. These are locally called "Sea apples" or "Sea cocoa-nuts." They are the fruits of the Bussu palm (*Manicaria saccifera*), found in Trinidad and the adjacent mainland of South America. The white kernel is sometimes fresh enough to be eaten after long immersion in salt water. This fruit was gathered by Sloane as long ago as 1687, and he remarked that it was frequently cast on the north-west islands of Scotland by the currents and the sea. The seeds of the Cocoon (*Entada scandens*), large brown beans about two inches in diameter, are so frequently cast ashore in various parts of the world, that they are commonly called "Sea-beans." Several plants have been raised at Kew from seeds picked up at the Azores. It is also mentioned by Robert Brown that a plant of *Cæsalpinia Bonduc* was raised from a seed found stranded on the west coast of Ireland. Linnæus also seems to have been acquainted with instances of germination having taken place in seeds thrown ashore on the coast of Norway. These are well-known and familiar examples of drift-fruits. The record might be considerably enlarged without more than touching on the fringe of the subject. It is hoped that botanists in suitable localities will give attention to this comparatively unworked field of investigation, and record the results of their observations.

In NATURE (vol. xxxix. p. 322), I gave an account, with woodcuts, of a drift-fruit that was collected on the shores of Jamaica. This had a very singular history. It had, in the first instance, been gathered nearly three hundred years ago, and presented by Jacob Plateau to Clusius. It was figured and described by many of the older botanists, but up to the time of writing in 1889 the plant bearing it had not been identified. The object I had in view in drawing attention to it in the columns of NATURE, was to enlist the interest of those likely to throw light upon its origin, and lead eventually to its identification.

FORMER HISTORY.

It is somewhat remarkable that a drift-fruit so plentifully brought by the Gulf Stream, and cast ashore in the West Indies and elsewhere, should have been so long a mystery.

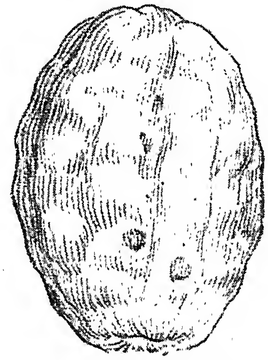
The first notice, so far as I can gather, is given with a woodcut, by Clusius, in his "Exoticorum libri decem," lib. ii. cap. 19. This work bears the date of 1605. The following is Clusius' description, which is reproduced as it appears in the original, together with his representation of the fruit:—

Exotici fructus à Jacobo Plateau & aliis accepti.

Cap. xix.

Aliquot exoticos fructus mittebat ad me Jacobus Plateau, quum intelligeret me Exoticorum Historiam scribere, ut quantum posset meos conatus etiam in hac materia juvaret, sed quos, præter binos, jam antè videram & descripseram.

Binos igitur illos, quos dixi mihi antè non fuisse conspectos, cum binis aliis aliunde acceptis, in tabella exprimi curabam quam hîc subjicio. Primus illorum quos Plateau mutuo dabat, binas uncias cum semisse longus erat, quatuor in ambitu crassus, cine-



Drift-fruit (after Clusius).

racei coloris, quem aliquo operimento tectum fuisse arbitrabar: in quinque partes dividi posse, venæ per longitudinem ductæ indicabant; alioqui eminentibus aliquot tuberculis instar vesicularum obsitus erat, quæ aperta, inanes & inæquales lacunas ostendebant spadicei coloris & splendentes, quasi semen aliquod continuissent: valde durus autem erat is fructus, & adstringente facultate præditus.

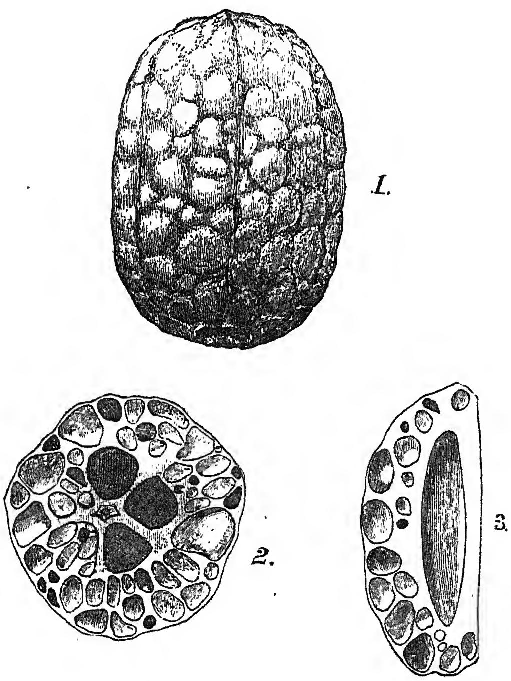
About sixty years afterwards, Johannes Jonston, in "Historia Naturalibus de Arboribus et Fructibus" (1662), p. 102, refers to the same fruit. In 1680 both the description and figure given by Clusius were reproduced by J. Bauhin in "Historia Plantarum," tom. i. lib. 3, cap. cxi. fig. 1. It is next mentioned in Sloane's "Catalogus Plantarum" (1696), p. 214, in the following words: "Fructum nunc saepissime collegi in Insulæ Jamaicæ littus ejectum cum aliis maris recrementis." The fruit itself was recognised in 1889 by Mr. E. G. Baker, as existing in the Sloane Collection in the British Museum (Natural History) where it is labelled "No. 1656." Further, in 1764, a small and somewhat unsatisfactory figure was given in "Petiveri Opera," t. lxxi., fig. 5, with the information: "It is a hard oval fruit with seed-holes round its surface. Cat. 605. Found on the shores of Jamaica." In all the cases enumerated above, it is represented in its water-worn condition as given in Fig. 1 below. It is a hard bony fruit, about an inch and a half to two inches long, marked externally with mammillated protuberances corresponding (as shown in Figs. 2 and 3) with numerous cavities or resin-cysts existing in its walls. In the transverse section, Fig. 2, it may be seen that the fruit is normally five-celled, but two are suppressed. The seeds are solitary, and contain abundant albumen. There is no doubt it was once a drupaceous fruit, but the fleshy outer layer or sarcocarp has decayed or worn away by the action of water. What is now left is, in many respects, so unlike the fruit in the fresh state, that its origin must always have been somewhat difficult to trace.

In passing, it may be noticed that it possesses ideal qualities as a drift-fruit. The numerous closed cavities contained in the walls render it very buoyant, and easily influenced by the action of the wind, while its hard texture and the presence of resin preserve it from becoming water-logged or decayed. There is no record that the seeds have germinated after long immersion in salt water, or that the plant has established itself in a new locality outside its present area. These are interesting points for further observation.

RECENT HISTORY.

The chapter in the recent history of the fruit opened in 1884. It was then collected, by the writer, with other drift-fruits on the sandy-spit of land known as the Palisadoes enclosing Kingston Harbour, Jamaica. On this land the Botanical Department had

established a cocal or cocoa-nut plantation with about 25,000 trees. Many of these are now in full bearing, and bring a regular revenue to the Government. The locality is exposed to the full force of the waves from the Caribbean Sea, and large quantities of wreckage, sea-weeds, and drift-fruit are thrown high up on the beach. The drift-fruits collected in 1884 were forwarded to Kew, and most of them were easily determined. The fruit under notice was, however, quite new, and it was placed in a cabinet with others until sufficient material had accumulated to lead to its identification. In November 1887, a further specimen was sent to Kew, by Mrs. Hubbard. This, singularly enough, had been picked up on the shore of Bigborough Bay, in the south of England. It is quite possible in this instance it may have been derived from a wreck, or thrown overboard from a passing ship, but, as Mrs. Hubbard aptly remarks, "such a fruit is not among the usual articles of import, and further, our south-west coasts are very likely to receive Gulf-stream waifs and strays." It was still, however, undetermined. The presence of the resin-cysts was always regarded as a character of some value. From the large collections in the Museums of Economic Botany at Kew a clue was at last obtained by the assistant, Mr. J. M. Hillier, in



Representation of a Jamaica drift-fruit (natural size). 1, external aspect; 2, cross-section; 3, longitudinal section.

the fruits of *Humiria gabonensis*, belonging to the natural order *Humiriaceæ*. These were somewhat smaller and more globular than the Jamaica drift-fruit, and, being covered with a brown fibrous epicarp, looked very different. The bony endocarp was, however, similar in character and plentifully furnished with resin-cysts. The natural order *Humiriaceæ* is a small one, and consists of plants entirely confined to tropical America, with the single exception of the species already mentioned. The theory was that the drift-fruit had been derived from tropical America, and not from Africa. The American genera of *Humiriaceæ* are *Vantanea*, *Humiria*, and *Sacoglottis*. The balance of probability at the time was in favour of *Humiria*, and possibly of *H. balsamifera*. The fruit of the latter was, however, unknown. After the publication of the note in NATURE special attention was given to the subject, with the result, as shown later, that the mystery connected with it was completely solved.

In 1887, Colonel Feilden, a member of the West India Exploration Committee stationed at Barbados, found a specimen on the beach of that island, while two years later Dr. H. A. Alford Nicholls, of Dominica, fished up a similar specimen off the sland of Mustique, between St. Vincent and Grenada.

The most important result was, however, obtained from the island of Trinidad. In March 1889, Mr. J. H. Hart, Superintendent of the Botanic Garden at Trinidad, wrote as follows: "I am extremely pleased that you called my attention to the Jamaica drift-fruit. I remember the specimens well, and cut several of them in Jamaica at the time we were packing the set you sent to Kew for the *Botany* of the *Challenger* Expedition. As soon as I read your article in NATURE, I commenced a search among the material in the herbarium here, and found a drawing of *Sacoglottis*, by Crüger,[1] with dissections of the flower and fruit. These made it evident that the plant which produces the unknown fruit is a native of Trinidad. Feeling further interested in the matter, I communicated with Mr. Syl. Devenish, the friend and companion of Crüger on many of his excursions, and I learnt further particulars as follows. When travelling in the forest at Irois, in the south-eastern part of the island, they found on the beach specimens of the fruit in question. Following up the stream they came to the tree producing it, from which, I presume, the drawings were taken. In addition, Mr. Devenish gave me a fruit, which I now send, to show there can be no mistake in the matter. This was collected by himself on the spot, so that there can be no doubt of the identity of the species we are both discussing. Mr. Devenish states that the tree is very rare. He saw but two in all his travels through the island. It is known locally as *Cojon de Burro*. It is probable that a greater portion of the drift-fruits found in Jamaica and elsewhere are produced on the mainland of South America, and are brought down by the flood waters of the Orinoco and the Amazon." On receipt of Crüger's drawings, Prof. Oliver at once expressed the opinion that they afforded a satisfactory solution of the problem. He stated: "The fruit of *Sacoglottis amazonica* is unknown, but Crüger's drawings correspond well with the floral analysis of the plant given by Dr. Urban." The latter monographed the *Humiriaceæ* in Martius' "Flora Brasiliensis."

It may be mentioned, in passing, that Dr. Urban had already ventured an opinion that the fruit might belong to *Sacoglottis*, but there were no fruits available for comparison in the herbaria at Kew, Berlin, or Paris.

The *Humiriaceæ* consist of trees or shrubs mostly with balsamic juice. The Balsam of Unieri, possessing the properties of Peruvian and Copaiva, is the produce of *Humiria floribunda*. A preparation of the juice of this and *H. balsamifera* has the odour of Storax, and is made into ointment and used internally. Although very different in habit, the *Humiriaceæ* are not far removed from the Flax order, *Lineæ*.

Sacoglottis amazonica is a moderately large tree, thirty to forty feet high, with a stout stem of an ash-grey colour. The leaves are alternate, slightly crenulated along the margin, and with two small glands at the base. The flowers are arranged in lateral panicles, petals yellowish-green, the anthers are ten in number, five long, five short, joined at the base. There is an annular disk closely girding the base of the ovary; the latter is five-celled, with a solitary ovule in each cell. The fruit was unknown until recently. It is described for the first time below.

Crüger's drawings, so thoughtfully sent by Mr. Hart, consisted of two sheets of dissections, with descriptive notes, all apparently done on the spot. They are minutely drawn, and give characters that are omitted even in the elaborate drawings in the "Flora Brasiliensis." They remind one of the careful field notes and sketches made by Sir Joseph Hooker in the Himalaya, by the late Dr. Thwaites in Ceylon, by Sir John Kirk in tropical Africa, and Mr. C. B. Clarke in India. The more recent botanical explorers are in no way behind their predecessors in regard to the skill and energy shown in selecting and drying their plants; but it may be mentioned, without disparagement of their invaluable services to science, that they do not, as a rule, devote the same attention as the older botanists to field notes and dissections, and thus a large amount of very interesting and accurate information is lost. Such information can never be obtained from the specimens themselves, however well they are mounted, in our National herbaria. It is certain that but for Crüger's drawings in this instance we should not, even now, have had the means of determining the origin of the Jamaica drift-fruit.

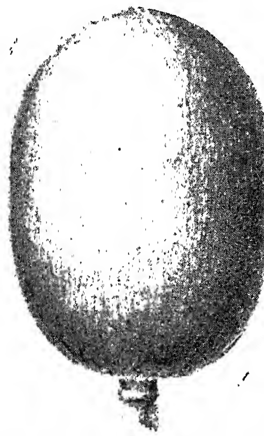
Since 1889 it has been sought to obtain fresh fruits of *Sacoglottis amazonica* from Trinidad or South America. These, so far, have not been received. There can, however, be no doubt of the identity of the plant. In order to obtain final evidence on the subject, my colleague, Dr. Stapf, the Assistant for India

[1] Dr. Herman Crüger, formerly Colonial Botanist and Superintendent of the Botanic Gardens, Trinidad.

in the Kew Herbarium, has been good enough to undertake a critical examination of Crüger's drawings, and compare them carefully with the description and plates of the species in the "Flora Brasiliensis." The result of the investigation is contained in the following note :—

"Crüger's drawings of *Sacoglottis*, Mart. 'Cojon de Burro,' October 13, 1861, agree perfectly with *Sacoglottis amazonica*, Mart. ('Flora Brasiliensis,' vol. xii. pt. 2, p. 449, tab. xcv.) The analyses are very carefully done. The sketch of the base of the leaf, for instance, shows the characteristic two glands which had been overlooked by Martius as well as Urban. As the fruit has not been previously described, it appears desirable to give a description of it drawn up from Crüger's drawings, as well as from the several specimens in the Kew Museum.

"Fructus subdrupaceus, ellipsoideus, $1\frac{1}{2}$-$1\frac{3}{4}$ poll. longus, 1-$1\frac{1}{4}$ poll. latus, exocarpio vix 1 lin. crasso, endocarpio osseo, extus subbullato, cavernis resina impletis abundante, 5-loculari vel saepius ob ovula loculosque 1-4 aborta 4-1-loculari ineunte



Fruit of *Sacoglottis amazonica*, Mart. (after Crüger).

germinatione valvis 5-trigonis ab axi 5-alata semina inter alas in loculis late apertis exhibente sedentibus dehiscente. Semina cylindrica, pollicaria, testa tenui nigro-brunnea, albumine carnoso, embryone centrali, cotyledonibus lineari-oblongis planis, radicula brevi supera.

"The breaking up of the fruit, as described above, takes place also in water-worn specimens, as shown in the fruit collected by Dr. Nicholls. *Sacoglottis amazonica* was previously known only from Teffe or Egas, on the right bank of the middle Amazon, and from the banks of the Tagipurú, a channel in the delta of the Amazon, where it was collected by Martius. It is recorded from St. Vincent, on the authority of Guilding. Specimens from the latter are in the Kew Herbarium, but whether from wild or cultivated plants is not stated. It is also not certain whether they did not come, as many of Guilding's specimens, from Trinidad."—O. STAPF.

SUMMARY.

The story of this interesting drift-fruit is now told. The record of its occurrence has been traced from the year 1605, when it was first figured and described by Clusius, down to 1764, when it was redrawn by Petiver. For about one hundred and fifty years it was successively described by Clusius, Jonston, J. Bauhin, Hans Sloane, and Petiver. From 1764 until 1884, a period of one hundred and twenty years, it appears to have been entirely overlooked. It was, however, once more brought into notice in the latter year, and drifted specimens were obtained within a short period from Jamaica, the South of England, Barbados, the Grenadines (between St. Vincent and Grenada), and Trinidad. The specimen from the latter island was accompanied by careful drawings made by Crüger in 1861, giving particulars not only of the fruit itself, but also of the leaves and flowers. These when carefully compared with the description and plate in the "Flora Brasiliensis," and with specimens in the Kew Herbarium, left no doubt that the plant yielding the Jamaica drift-fruit is *Sacoglottis amazonica*, Mart. This grows very sparingly in the south-eastern portion of Trinidad, where it was collected by Crüger, but is more abundant in the delta of the Amazon, where it was collected by Martius and others. It is evident that from one or both of these localities the fruits are carried by the waters of the Gulf Stream into the Caribbean Sea, and either thrown ashore on the West Indian Islands, or carried still further, as in the case of many other similar fruits, across the North Atlantic, and cast on the shores of Western Europe. D. MORRIS.

THE PERCEPTION OF LIGHT.[1]

AT a former anniversary I brought before the members of the Institute the subject of the luminiferous ether. It is one of great and growing interest. I mentioned on that occasion how discoveries of very recent date have led us to attribute continually increasing importance, and a widening range of function, to that medium—substance can I call it ?—the existence of which was originally assumed as a hypothesis in order to account for the phenomena of light. It is in connection with this last aspect that it relates to what I propose to bring before you to-day.

The wonderful sense of sight, which, to use an expression of Sir John Herschel's, confers upon us to some extent the character of ubiquity, requires two things: in the first place, some means by which those distant bodies which we see are able to affect our own neighbourhood ; in the second place, some provision in our own bodies for receiving that influence, and transmitting some sensation to the conscious being.

In my former address I considered the first of these two subjects ; to-day I mean to confine myself to the second. This second, even by itself, is, however, far too wide for a single address ; selection of some kind is imperatively demanded. Moreover, there are some parts which are accurately known, and may even be made the object of mathematical calculation, while there are others which not merely lie beyond our existing knowledge, but beyond any that we can hope to attain to, at least in this life. Wonderful as is the construction of the eye in all its parts, so far as relates to the formation of images on the retina it acts simply like an optical instrument, like a telescope or microscope, or, more correctly, like the objective of such an instrument, and we may apply our mathematics to tracing the course of the rays through it. On the other hand, even if we knew accurately—which we do not—the nature of the effect which the external agent produces on the ultimate structure of our bodies, there would still remain, shrouded in impenetrable mystery, the nature of the process by which some change in the bodily organism causes a sensation to the conscious being.

Between these two extremes lies a region which has been to some extent explored, and in which a gradual and perhaps at last a very substantial increase to our existing scientific knowledge may be looked upon as probable. The investigation of this region possesses the keen interest which belongs to the discovery of new truths, and the addition thereby made to the stock of human knowledge. It is to this borderland lying between the well known and the unknown, and to certain parts of the structure of the eye having relation to it, that I would for a short time direct your attention to-day.

As I have already intimated, I propose to pass by entirely the functions of the eye acting as a simple optical instrument in forming images on the retina. The explanation of that may be found in all the ordinary text-books, and I will not weary you by repeating what is there to be found, and which is generally familiarly known.

The phenomena of vision show that distinctness of vision is dependent somehow or other in the first instance on the formation of distinct images of external objects on the retina. In that formation, as I have said, the transparent portion of the eye, the cornea, the aqueous humour, the crystalline lens and vitreous humour, plays the part of a lens in an optical instrument. I have said the "formation of the images on the retina" ; but the retina is not a mere surface, it has a certain amount of thickness, although it is, on the whole, very thin. We may further inquire on what part of the retina, considered at different depths from the place where it first commences, on which of the various layers into which histologists have divided it, is it that we have reason to think that light first acts on the organism of our bodies in such a manner as ultimately to give us the sensation of vision?

I have said that the retina, as a whole, though very thin, is not a mere surface. If we go from the centre of the eye-ball

[1] Presidential Address delivered at the Victoria Institute by Sir G. G. Stokes, F.R.S.

outwards, *i.e.* towards the back of the body, we have first a plexus of very fine nerve-fibres which run along the front of the retina, and ultimately unite in the optic nerve, which runs into the brain. We have also minute blood-vessels, which are essential, apparently, for the growth from its original state, and for the nutrition of the eye-ball, and for the carrying on of the process for which it was designed, viz. that of enabling us to see. Then we have several layers of pulpy transparent substances which have been called ganglions, nuclei, and molecules, mixed with very fine fibres. Some of these are nerve-fibres, others are believed by anatomists to have relation to the fixing of the various parts of the structure to one another, so that they shall not fall to pieces in the rapid motions of the person using the eye.

Outside all, at the back surface of the retina, there is what is called the choroid coat; but between that and the coats I have spoken of is a very remarkable structure which I shall have to say more about. It is called the *bacillary* layer. In this part of the retina we have a vast number of elongated bodies placed closely, side by side. In the human eye, and in the eyes of most animals, they are of two shapes, and have been called accordingly rods and cones. The rods, as the name implies, are cylindrical, and the cones are tapering and are somewhat of the shape of slender peg-tops, the sharp side being turned inwards as regards the way you look, so that the light, in coming from the outside, first meets the bases of the peg-tops, and then goes on towards the point. About the point of these rods and cones, just close to the choroid coat, is a layer of pigment cells which absorb the greater part of the light falling upon them. The rods and cones are transparent, and allow the light to pass through them, passing lengthways. I said the extremities reached to the layer of pigment cells forming a black lining immediately inside the choroid coat. That is true of the rods, but the cones do not reach quite so far, *i.e.* when the eye is in a state of repose, as in darkness; but under the stimulus of light these pigment cells come down, *i.e.* forward, in the direction in which you look, so as to reach the tops of the cones as well as of the rods. I have said that these elements (remember, please, that they point radially in the direction in which you are looking, and lie side by side) are exceedingly numerous. When they are looked on lengthways from the back of the eye when the pigment is removed, they form a sort of mosaic. You may imagine the general structure of them by thinking of the head of the common sunflower in seed. They are arranged side by side, something like the seeds of the sunflower; but they lie so close that the distance between the neighbouring rods or cones, as the case may be, is only about (it varies somewhat from one part of the eye to another) $\frac{4}{1000}$th part of a millimetre, or say about $\frac{1}{6000}$th part of an inch. So numerous are they that a square with sides the tenth of an inch would cover nearly half a million of them.

Now something more about these rods and cones. They are found to be composed of two members or limbs, an inner (nearer the centre of the eye-ball) and an outer. The inner is a transparent-looking body, very much like the other bodies in the neighbourhood. The outer is transparent too; but it is found to be highly refractive. It is longer in the rods than in the cones. The outer segment of the cones may be represented to the mind's eye by thinking of the metallic point of a peg-top. These outer limbs are in both cases readily detached (when the eye is dissected) from the inner, and they separate after a little into laminæ, lying one on the top of the other, perpendicular to the axis of the rod or cone. At the outer end they do not appear to have any continuation, the structure stops. At the inner end (corresponding in the case of the cones with the bulbs of the peg-tops) there come nerve fibres from each of them. These pass through the various layers that I have spoken of; and although the course of them has not actually been traced the whole way, on account of the difficulty of examination of this pulpy structure, it is pretty certain that they join on to those nerve-fibres which line the front surface of the retina, and so pass on, through the optic nerve, to the brain. When I say "pass on" I mean of course as you trace them along; there is no motion in the case. This is a very remarkable structure. Has it any object? What is its object? Now we know by experience that if we have a single point of light exposed to us, the impression is that of a single point of light in the field of view. If there be two such points we have the impression of two luminous points occupying different positions in the field of view. Now two such points may be very close to one another, and yet we still see them as two. It is found that the limit of closeness, beyond which we are unable to distinguish two objects as two, is such that a line drawn between them subtends at the eye an angle of about one minute, or an angle of about $\frac{1}{30}$th part of that subtended by the diameter of the moon. Yet although they exist as close as that, the impression of the two is distinct, and we might have a number of points, each giving a distinct impression. It appears, therefore, that for the purpose of vision it is necessary that stimulations coming from a vast number of independent points, having different bearings from the eye, should, somehow or other, give rise to distinct impressions.

Now if by calculation we trace inwards, to the retina, the course of the axes of two pencils coming respectively from two distant points not far from the centre of the field, it is found that those axes intersect, not exactly in the centre of the eye-ball, but in a point (called the optical centre) a little in front of it, the position of which we can calculate; and the place of either image may be found by joining the external point with the optical centre, and producing the joining line to meet the retina. It is an easy matter now to calculate the distance on the retina of the images of two external points which subtend at the eye a known angle; and it is found that when the external points are so close as only just to be seen as two, the distance of the two images is about the $\frac{4}{1000}$th of a millimetre, just about the distance apart of the cones and rods from one another, lying so closely as I have explained they do. Here, then, it would appear, in this remarkable layer of the retina, we have a provision enabling us to have distinct sensation of a vast number of distinct points in the field of view; and consequently we have reason to suppose that the effect of light, whatever it be, on one of these elements (be it cone or be it rod) gives rise to the sensation of a point; and that the position of that point in the field of view depends upon the position of the element of the bacillary layer which has been affected by the light coming from the point. Moreover in the nerve-fibres which come from the anterior ends of the rods and cones we appear to have a provision for communicating, through the optic nerve, to the brain, the influence, or an indication of the influence which light exerts on one of these elements.

Now I have mentioned one argument for believing that this remarkable bacillary layer is that in which light, which previously merely passed through the eye as it would through an optical instrument, acts in some manner on the organism so as to give rise to stimulation of the nerves which convey to us the sensation of vision. The argument, so far, is a sort of *à priori* one, but it has been remarkably confirmed by an experiment of H. Müller's, made by means of Purkinje's figures.

When in a room which is not quite dark we look with one eye towards a moderately illuminated wall with uniform surface, and holding a candle to one side of the eye move it up and down, there is seen in the field of view a figure branching like seaweed. This is the shadow of the blood-vessels of the retina. That the candle requires to be moved in order to show the figure, is explained by the consideration that the shadow is not black, but only darker than its neighbourhood, and when the light is steady the exhaustion of the eye for that part of the field which lies beside the shadow tends to equalise the apparent illumination of the parts in and out of shadow; whereas when the candle is moved the shadow falls on a new place which had been in full light and therefore partially exhausted, and the previous exhaustion and the new partial interception of light falling on that place contribute to make the shadow sensible.

The existence of a shadow shows already that the percipient layer of the retina must lie behind the blood-vessels. But we may go a step further. By suitable methods of illumination we may cause two spots on the surface of the eye-ball, whose positions can be determined from the circumstances of the experiment, to be alternately virtually the sources of the light which casts the shadow, and the places in the field of view of the shadows of the same vessel in the two positions of the illuminating source can be marked. It is then only a question of similar triangles to determine how far behind the blood-vessels lies the percipient layer, and the distance thus calculated is found to agree, within the limits of errors of observation, with the distance of the bacillary layer as determined by microscopic examination of a dissected eye.

I have said as you go backward from the centre of the eye-ball, you have, in front of the rest of the retina, a plexus, as it is called, of nerve-fibres lying side by side, something like the threads in a skein of silk, but gradually leading onwards to the

optic nerve. Light passes across these, but it does not excite the nerves in passing through them. The nerves are transparent, and the light produces no effect upon them directly. If it did, your whole field of view would be confused, because it is known that when a nerve is excited the sensation is referred to a particular part no matter where the nerve may be affected. Suppose you could isolate, say in the thigh, a particular nerve leading to the great toe, and pinch it without hurting its neighbours, you would feel the pinch not where the nerve is pinched, but in the great toe. So, here, if these nerve-fibres were excited by the passage of light through them, then the sensation corresponding to the excitement of a particular nerve-fibre, which would be that of a definite point in the field of view, would be excited by an external luminous point lying anywhere in the curve in which the surface generated by a straight line passing through the optical centre and intersecting the fibre in question would cut what we may call the celestial sphere, and the correspondence between the subjective points in the field of view and objective external points would be lost. And the fact that the visual nerves are not affected by light which passes across them is further shown by the well-known experiment of the blind spot, where the optic axis passes out of the eye-ball, not in the axis of vision but to one side, towards the nose, so that an object whose image falls on the blind spot of one eye is seen by means of the other.

But now comes a question, and here we enter on uncertain and debated ground—How is it that the nerves are stimulated by the light at all?

We have reason to believe that these rods and cones form the means by which the light, acting on them, causes the stimulation of the nerve. As I have said, they consist of two elements, an inner and outer; the outer from the centre of the eye, *i.e.* the inner as regards the body, being of that remarkable structure which I have described. It has been questioned which of these two elements it is that you are to regard as the percipient organ. I do not know that physiologists have decided that question. I have looked into a paper of Max Schultze's—in fact I have it on the table—and he inclines to the opinion that it is the outer element. Now is there anything in the outer element which can conceivably form a means of stimulation of the nerve, when that element is acted on by light?

I have spoken of the way in which it is composed of laminæ which come to pieces when dissected, after a certain amount of maceration. I do not know whether it may not be rash to say what I am about to say, because I do not know that physiologists have suggested it—it is merely an idea which occurred to myself, so you must take it for what it is worth. I was reading an account of the electric organ of electrical fishes, such as the torpedo. It is a very remarkable organ, occupying a considerable space in these fishes. It has a columnar structure, and the column again consists of laminæ placed one over the other. It has a structure which may roughly be compared to that of the basaltic columns in the Giant's Causeway, only here you must think of laminæ as more numerous and not having that curved surface shown in the Giant's Causeway. Now nobody questions that somehow or other this is an organ by means of which these fishes are enabled to give a shock, and the idea, of course, is suggested, are not these laminæ like the plates of a battery? Is not one of these columns, roughly speaking, something like a galvanic battery? But how the battery is charged and discharged we do not know. In this case it depends, no doubt, on the will of the animal as to what he does, and nobody knows how he brings that about.

Now it strikes me that there is a remarkable apparent analogy between the outer member of the rods and cones, and these columns in electrical fishes. This gives rise to the suspicion that possibly these outer members may act the part of a microscopic battery, being charged somehow or other. But how are they to be charged? Well, before I go on to enter into any speculation on that I may mention that some years ago Prof. Dewar and Mr. McKendrick made some remarkable experiments, the results of which are given in a paper published in the *Transactions* of the Royal Society of Edinburgh. When an eye is dissected out, and the cornea is connected through a wire with non-polarising electrodes to the middle of the section of the optic nerve, the wire being led through a delicate galvanometer, it is found that there is a certain amount of electric current passing. Now it was found that when the eye (having been in darkness) was allowed to have light shining upon it, there was a change in this current, and a change again when the light was cut off. It is true that the total change was only a small fraction of the whole; but still that there should be any change at all produced by the action of light is a remarkable thing. It looks very much as if the stimulation of the nerve had something or other to do with the production of electric currents; but those, if they are produced, we must suppose to be produced in some way by the action of light. How may we imagine light to act so as to produce them? It has been discovered that in the layer of pigment cells in the retina there is a substance, called visual purple, of a purple colour, which is acted on by light, and is made first yellow and then nearly colourless. We have thus a substance that is capable of being acted upon by light, as very many substances are. I do not say that it is by any means proved that that is the substance, or even that there is any substance, which is acted upon by light in the way demanded; yet it seems very probable that the change produced by the action of light, whether it be on visual purple, or some other substance associated with it, may give rise to something which may, so to speak, charge this microscopic battery and stimulate the nerve-fibre which is attached to it. We know the rate of the vibrations of light of various kinds; and the rapidity of vibrations is so enormous, ranging about 400 millions of millions of vibrations in a second, that we can hardly imagine that the organism of our bodies is calculated to be set in vibration in a corresponding period. In that respect the sense of sight differs notably from the sense of hearing. In hearing the tympanum of the ear is thrown into vibration, and the vibrations are not so enormous in number in such a time as one second but that the corresponding nerves may actually be mechanically agitated, and thereby in some way stimulated. We can hardly imagine that the visual nerves are acted upon in this sort of way directly by the luminous vibrations, but they may be indirectly. Here, again, I may throw out a possible conjecture, though I am less disposed to receive it myself than that which I have just mentioned. We know there are substances which when acted upon by light continue to shine in the dark. In some cases the action ceases almost instantly after the exciting light is cut off; for instance, a solution of the salts of quinine, where the rapidity of cessation of the effect is amply sufficient to tally with the rapidity of cessation of visual sensation when light is cut off.

There are various other matters connected with the perception of light which are of great importance to our well-being and to our enjoyment which I have not ventured to touch upon at all. It would take a great deal too long to go into two which I will only just mention. One is the provision in the two eyes, and in the muscles which move them, which enables us to obtain single vision notwithstanding that the two eyes are at work. Nothing is easier than to obtain double vision in which the images seen by means of two eyes occupy different positions in the field of view. There are very remarkable contrivances for bringing about singleness of vision in the habitual use of both eyes.

Then, again, we do not see light merely as light, but we see a great variety of colour. We can distinguish one light from another light by its colour, and not by its intensity only. It would take me a great deal too long to give you any idea of what is known (which after all is not much) as to the way in which that is effected.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Woodwardian Museum has been greatly enriched by the generosity of Prof. T. Wiltshire, Treasurer of the Geological Society and Secretary of the Palæontographical Society, who has presented to the University a large collection of Cretaceous fossils. The collection includes nearly all the known British species, as well as many not yet described. This addition will probably make the Woodwardian collection of Cretaceous fossils the finest in the country. The thanks of the University have been voted to Prof. Wiltshire, who is himself a Cambridge graduate.

Sir William Turner, F.R.S., of Edinburgh, has been appointed an Elector to the chair of Anatomy, and Lord Walsingham, F.R.S., an Elector to the chair of Zoology and Comparative Anatomy, in place of the late Right Hon. T. H. Huxley.

The Vice-Chancellor, Mr. C. Smith, Master of Sidney Sussex College, is suffering from the shock of a fall from his bicycle last week, and will probably be unable to resume his duties for some

time to come. We learn, however, that he is making satisfactory progress towards recovery. The Provost of King's College, late Vice-Chancellor, is acting for him.

DR. A. WEISMANN has been granted the degree of Doctor *honoris causâ* by the University of Utrecht.

Science states that at the annual meeting of the Chicago Alumni of Mount Holyoke College, on October 24, Dr. D. K. Pearson offered to give £30,000 to the College, provided the alumni would raise an additional £10,000.

A MEMORIAL from the London School of Medicine for Women was considered at a meeting of the Council of the Royal College of Surgeons of England, last week, and it was resolved that—"The Council of the Royal College of Surgeons of England, although in favour of granting the petition of the officers and teachers of the London School of Medicine for Women, do not see their way to admit women to the Conjoint Examination in face of the adverse vote of the meeting of the Fellows and Members of this College and the expressed opinion of the Royal College of Physicians."

AT a meeting of the Council of University College, Dundee, on Monday, the question of the relations of the college to St. Andrews University was considered. It was decided to address a letter to her Majesty's Commissioners expressing the willingness of the Council to consider carefully any suggestion from the Commissioners with a view to removing the difficulties in which, by recent events, the University and the college had been placed, and in particular to meet the Commissioners and the University Court to discuss anew any proposals which might form the basis of a new agreement between the two institutions and secure to each the advantages provided for in the Universities Bill of 1889.

THE following are among recent appointments:—Prof. S. L. Barton to be professor of mathematics in the University of the South, Seewanee, Tennessee; Dr. A. Macfarland to be lecturer in physics in Lehigh University; Dr. G. B. van Vleck to be associate professor of mathematics in Wesleyan University; Prof. C. A. Waldo to be professor of mathematics at Purdue University; Prof. K. Zickler to be professor of technical electricity in the Technische Hochschule at Brünn; Dr. R. Dzieslewski to be professor of the same subject at Lemberg Technische Hochschule; Dr. F. Mehres, extraordinary professor of physiology in the Bohemian University at Prague, to be professor; Dr. F. R. von Höhnel to be professor of botany and technical microscopy in the Technische Hochschule at Vienna; Dr. H. Klinger to be professor of chemistry at Königsberg; Dr. E. Waelsch to be extraordinary professor of mathematics in the German Technische Hochschule at Brünn.

A CONFERENCE of the leading teaching and examining bodies of the kingdom and of representative County Councils which are in a position, under the County Councils Act, to contribute funds for the purpose of technical instruction, was held last week, under the auspices of the London Chamber of Commerce, at Drapers' Hall, Sir Albert K. Rollit (President of the Chamber) presiding. The conference agreed to a resolution approving the principle of the co-ordination and simplification of the present system of examinations in commercial subjects, and the matter was referred to the Commercial Education Committee of the London Chamber of Commerce to consider details and formulate a scheme to carry this resolution with effect, it being understood that the Chamber would enlarge its Committee for this purpose by the addition of some members of the conference. Perhaps now that the Chamber of Commerce has taken steps to organise commercial education, it may go on, and, in the course of time, do something for instruction in science.

FROM statistics in the *Deutscher Universitäts Kalender* it appears that the number of persons attending lectures in German universities during the winter semester of 1894-95 was 33,021, of whom 8755 were in attendance at Berlin, 1587 at Bonn, 1350 at Breslau, 1168 at Erlangen, 1216 at Freiburg, 556 at Giessen, 843 at Göttingen, 775 at Greifswald, 1643 at Halle, 1230 at Heidelberg, 667 at Jena, 532 at Kiel, 737 at Königsberg, 3112 at Leipzig, 852 at Marburg, 3561 at Munich, 421 at Münster, 420 at Rostock, 980 at Strassburg, 1184 at Tübingen, and 1492 at Würzburg. At Berlin, however, the matriculated students numbered only 5631, the remaining 3724 being persons who had received permission to attend lectures without being enrolled as *cives academici*; at Leipzig there were 127 of such students, and at Munich only 86. In the law department (including cameralistics and forestry) there were at Berlin 1667, at Leipzig 985, and at Munich 1230 students; in the medical department (including surgery and pharmacy) at Berlin 1220, at Leipzig 752, and at Munich 1168; in the philosophical department (including philology, mathematics, &c.) at Berlin 1660, at Leipzig 856, and at Munich 700.

SEVERAL noteworthy points are referred to in the Report of the City and Guilds Technical College, Finsbury, for the session 1894-95, in addition to the usual statistics and statements as to the number and quality of the students and the work of the different departments. During the session a number of students entered the College with scholarships from various County Councils and other bodies. A few of these were able to obtain the full benefit from the instruction given, but some of them had gained their scholarships when too childish to benefit properly by the College system. Others suffered from imperfect preliminary training, having been crammed to pass examinations rather than trained how to learn. And the result of it all is that the Principal points out that care must be exercised in future, and influence brought to bear upon the educational advisers of the various County Councils as to their selection of scholarship holders. As a step towards the better selection of qualified candidates, it is proposed to introduce a slight modification into the entrance examination of the College. As with other Colleges on the same status, it appears that amongst the newly-admitted students every year there are a number who have never been taught to take notes, to write original descriptions, or even to use indices or books of reference. The presence of these students has been found greatly to retard the general course of teaching, and causes much waste of time. The time of lecturers and demonstrators is taken away from their proper work to teach the new students things which they ought to have learned at school. As a step toward remedying this matter, it is proposed in future to lay more stress upon the English subjects in the entrance examination, by giving them greater prominence, and by assigning higher marks for such as *précis writing* and composition. In concluding his report, Prof. Thompson has something to say about the future of the College. The large Technical Institutes which have sprung up during the past few years, in various parts of London, have affected the trade-classes at the College to a certain extent, and have also diminished the numbers of students attending the elementary classes. But these Institutes have only affected the elementary part of the work, and the indications are that the more advanced students from the elementary work of the Institutes should pass to the Technical College to carry it on. No institution in London is attempting to give in its evening classes instruction of so thoroughly scientific a character as is given at that College; the instruction is, indeed, admirably suited to supplement the work of the various Polytechnics. It is therefore proposed to develop the courses of special lectures given at Finsbury, and to raise the scientific standard of the evening class work, so as to make the College a focus for the higher branches of study, and for more specialised classes than those of the Technical Institutes.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, vol. ii. No. 1, October 1895.—The number opens with accounts of the proceedings at the second summer meeting of the American Mathematical Society, held at Springfield, Mass., on August 27 and 28, and of the proceedings at the meeting of Section A of the American Association, held at the same place, from August 29 to September 4. The papers at each meeting are given in abstract, and two of them are printed in full, viz. on the differential equations of certain systems of conics, by R. A. Roberts, and asymptotic lines on a circular ring, by Prof. Maschke. The results in the former paper are principally deduced by means of elliptic integrals and the first class of hyper-elliptic integrals, and from these are derived theorems concerning doubly infinite porisms of curvilinear polygons. The latter paper contains an application of elliptic functions to curves drawn on the surface of a circular ring.—Prof. F. Morley communicates a short note on a generalisation of Weierstrass's equation with three terms.—The notes contain various items of interest, and the list of publications is unusually full.

The Mathematical Gazette, No. 6, October 1895.—The conics of Apollonius, by the Rev. J. J. Milne, is the paper read by that gentleman at the annual meeting in January last. It contains a full and careful analysis of Apollonius' treatise, putting in evidence what the great geometer says on the subject, and also stating what properties he does not touch upon. The result arrived at is that the ground covered by Apollonius "is very extensive, and many parts of the subject are very thoroughly treated which are passed over in silence in modern text-books." —Proof of Horner's method of approximation to a numerical root of an equation by the properties of algebraical quotients and remainders, by Mr. M. Jenkins, is supplementary to papers read before the Association by Messrs. Langley and Hayward. —Dr. J. S. Mackay gives a further short note on Greek geometers before Euclid. Amongst the geometers slightly noticed are Œnopides of Chios, Anaxagoras, Democritus of Abdera, Hippocrates of Chios and Antiphon.—The notes contain some suggestions in mathematical terminology, by R. F. Muirhead; some trigonometrical identities, by the editor and J. H. Hooker; on Simpson's rule, by Prof. A. Lodge; and on division into classes and homogeneous products, by P. J. Harding.—A few questions and reviews complete a number which is quite up to the previous high standard of the *Gazette*. If this journal were better known, we feel sure it would be more heartily supported than it is by mathematical teachers.

Bulletin de l'Académie Royale de Belgique, No. 8.—On a hydrate of arsenic trisulphide and its decomposition by pressure, by W. Spring. If the specific volume of a compound is greater than the sum of those of its constituents, it should be decomposed by pressure. This has already been verified with cupric-calcic acetate. It is also shown by the hexahydrate of arsenic trisulphide, which decomposes on compression in water or orpiment, and does not require very great pressure. This phenomenon is the converse of the combination of bodies by pressure when the resulting specific volume is smaller.—On a spot recently observed on the surface of Venus, and on the period of rotation of this planet, by M. Schiaparelli. This spot is near the south pole of the planet, and had at the time of writing remained the same for four weeks, so that the period of about twenty-three hours is out of the question.—On the attraction sphere in the fixed cells of the conjunctive tissue, by C. de Bruyne. The author investigates the attraction sphere in the conjunctive cellules fixed in position in the interstitial of the liver and the genital glands of *Paludina vivipara*. He describes its constitution, its shape, its continuity with the cytoplasmic filaments, the character of the medullary zone and that of the centrosomes, which vary in number, dimensions and shape. He then describes the situation of the sphere and its relations to the nucleus, and the constitution of the radial fibres. He concludes, against the views of O. Hertwig and others, that the centrosomes rest in the cytoplasm during the stage of repose of the cellule. The drawings reproduced are a conclusive proof of their presence in the conjunctive cellules at rest.

THE papers in the *Bullettino della Società Botanica Italiana* for July belong exclusively to the departments of descriptive and geographical botany, most of them having special reference to the Flora of Italy.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, November 6.—The Right Hon. Lord Walsingham, F.R.S., Vice-President, in the chair.—Lord Walsingham announced the death of M. E. L. Ragonot, President of the Entomological Society of France, and, since 1887, a Foreign Fellow of the Entomological Society of London. He remarked that M. Ragonot was especially distinguished by his knowledge of the *Phycidæ*, a monograph on which group he had brought out in Russia, and for his amiable personal qualities and the readiness he showed to assist other workers in the identification of species. He said that the loss of M. Ragonot would be greatly felt not only by the Entomological Society of France, but by entomologists all over the world, and that the Council had that evening passed a resolution to the effect that the Secretary should write a letter of condolence to the French Entomological Society on the death of their distinguished President. Colonel Swinhoe also spoke as to the great loss sustained by the death of M. Ragonot, and of the kindness and generosity of the deceased, which he had personally experienced. —Mr. Goss read a letter from Mr. Waterhouse, calling attention to the prospectus of a monograph by Mr. Ernest Green on the *Coccidæ* of Ceylon. A copy of the prospectus and specimen plates were shown, and Lord Walsingham and Mr. McLachlan commented on the importance of the proposed work and the beauty of the plates.—Mr. Stevens exhibited two larvæ, supposed to be those of a species of *Anobium*, which had been damaging oil paintings in his possession; also two specimens of a luminous species of *Pyrophorus*, which he had received alive from the West Indies.—Mr. Adkin exhibited a portion of a collection of Lepidoptera made in Hoy, Orkney, in 1895, including the following species, viz. *Agrotis vestigialis*, *A. tritici*, and *A. cursoria*, not previously recorded from Orkney; *Nemeophila plantaginis*, having the usual yellow ground-colour of the hindwings replaced by red in many of the females; *Hepialus humuli*, males of the ordinary white form, bearing no resemblance to the Unst (Shetland) form; *Triphæna comes*, all very dark, the forewings almost black, the yellow of the hindwings of many of the specimens much obscured by blackish scales; *Noctua festiva*, showing forms of variation ranging between the pale southern and the dark *conflua* forms; *Epunda lutulenta*, some almost uniformly black, others pale grey with dark markings; *Hadena adusta*, one almost black, others much variegated; *Thera juniperata*, many having the central fascia and apical streak very dark brown; and *Hysipetes sordidata*, varying from blackish-brown to pale green.—Mr. Tutt exhibited a series of *Emydia cribrum*, var. *candida*, which he had bred from eggs obtained from a specimen caught by Mr. Merrifield in May 1895, in Northern Italy. He stated that being unable to obtain *Calluna vulgaris*, the ordinary food-plant, he had tried them with Knot Grass (*Polygonum aviculare*), and had no difficulty in rearing them.—The Rev. Canon Fowler exhibited, on behalf of Prof. Poulton, F.R.S., living *Diapheromera femorata* bred from eggs received from Prof. E. B. Titchener, of New York. He stated that the young larvæ had emerged from the eggs in July and August last, and fed on lime. Several pairs had arrived at maturity, and were feeding in cases in the Oxford Museum. —The Rev. J. H. Hocking exhibited a specimen of *Xylina zinckenii*, taken by him at sugar on the trunk of an oak tree, at Copdock, near Ipswich, on September 30 last. It was in beautiful condition, and had apparently only recently emerged from the chrysalis. He also exhibited two specimens of *Xanthia ocellaris* taken at the same time. Mr. Barrett referred to the few recorded chapters of *X. zinckenii* in this country.—Mr. R. W. Lloyd exhibited male and female specimens of *Amara alpina* from Garvell, Perthshire.—Colonel Swinhoe stated that he had, during the past summer, captured four specimens of *Pieris daplidice* at Deal. They were worn, and had probably been blown over from France. Mr. Tutt remarked that he had collected at Deal for many years, but had never met with *Pieris daplidice*.—Mr. Tutt read a paper by Prof. A. Radcliffe Grote, entitled "Notes on the genus *Cidaria*."—Dr. T. A. Chapman read a paper entitled "Notes on Pupæ; *Orneodes*, *Epermenia*, *Chrysocorys*, and *Pterophorus*." Lord Walsingham, Mr. Blandford, and Mr. Tutt took part in the discussion which ensued.

Geological Society, November 6.—Dr. Henry Woodward, F.R.S., President in the chair.—The Serpentine, Gneissoid and Hornblendic Rocks of the Lizard District, by Prof. T. G. Bonney, F.R.S. The author states that in company with the Rev. E. Hill, and in consequence of their work in Sark, he had again investigated the question of the genesis of the hornblende-schists at the Lizard, and was able to overcome the difficulties which formerly withheld him from attributing an igneous origin to the schists themselves, and their banded structure to fluxional movements during consolidation. There also, as in Sark, he found some evidence of this banding being the result, at any rate in places, of a mixture of a less and a more basic material. Additional evidence was given as to the genesis of the granulitic group and its relations to the hornblende-schist. The author maintained that the relations of the serpentine to the granulitic and the hornblendic groups are inexplicable on the hypothesis of an igneous complex, so far as he understood the meaning of that term, or of a folding in a solid condition or any other form of dynamometamorphism, and he maintained his original opinion that the serpentine (*i.e.* the original peridotite) was intrusive in the other rocks. The paper also dealt with some minor points in the geology of the Lizard. In the discussion that followed, Mr. Teall, speaking as to the origin of hornblende-schists, reaffirmed his belief in the theory that both gabbros and basic

dykes had been converted into rocks of this character by dynamic metamorphism; and Sir Archibald Geikie said that though he would not venture to offer an opinion upon most of the disputed questions in the geological structure of that area, he had seen evidence sufficient to convince him that in the Potstone Point part of the coast the serpentine and horblende-schist formed, as Mr. Teall maintained, the great complex which presented a marked coincidence of banding and had been plicated by one common series of movements. He could see no indication of the serpentine being intrusive in the schists.—The "schistes lustrés" of Mont Jovet (Savoy), by Dr. J. W. Gregory. The author gave a history of the controversy as to the age of the "schistes lustrés" of the Western Alps, making special reference to the views of Zaccagna and Bertrand concerning the schists of Mont Jovet. Of these writers, the former maintained that the rocks of the summit of the mountain are old rocks on which the Carboniferous and Triassic strata were deposited unconformably; while, according to the latter author, the rocks forming the top of the mountain were laid down after those which flank it. In his paper the present author gave the results of an examination of the rocks of Mont Jovet recently made by him. He contended that Lory and Zaccagna were correct in identifying the central rocks of Mont Jovet as "schistes lustrés," for this conclusion is supported by their lithological characters and the occurrence of basic igneous rocks of the "pietre-verdi" type associated with them, and is not opposed to their stratigraphical relations. It was further maintained, as the results of the evidence collected by the author, that the schists in question were older than the Trias. The probabilities were in favour of the schists occupying the same relation to the Carboniferous as they do to the Trias; while the close approximation of the schists to the former shows that the schists are not the altered representatives of the neighbouring Carboniferous beds, and it was therefore concluded that the "schistes lustrés" are pre-Carboniferous, but evidence by which finally to assign them to any exact horizon before this date is still wanting.

Linnean Society, November 7.—Mr. C. B. Clarke, President, in the chair.—Several volumes of Cryptogamic exsiccata, recently received from Madame Weddell as a bequest from her late husband, a foreign member of the Society, were shown, and some remarks made thereon by the Botanical Secretary.—A portrait of the French naturalist Guillaume Rondelet, Professor of Anatomy and Chancellor of the University of Montpellier 1545, recently presented to the Society by Dr. H. Woodward, F.R.S., was exhibited by the Zoological Secretary, who gave an account of his life and work, supplemented by remarks from the President.—Mr. C. T. Druery exhibited and made remarks on a *Scolopendrium* raised by Mr. E. J. Lowe, bearing archegonia and antheridia upon the fronds, constituting a more advanced phase of apospory than any previously noted. Some remarks thereon were made by Mr. George Murray.—Dr. Maxwell T. Masters exhibited specimens of the fruit of *Pyrus sorbus*, *Aberia caffra*, and small *Cocos australis*, from the gardens of Mr. Thomas Hanbury at La Mortola, Mentone, and some palm fruits of *Cocos australis* from Naudin's garden at Antibes, Alpes Maritimes.—Mr. J. E. Harting exhibited a specimen of the American yellow-billed cuckoo, which had been picked up dead in a garden at Bridport, Dorsetshire, on October 5, and gave some account of the species and previous occurrence in the British Islands.—A paper was read by Colonel Swinhoe on mimicry in butterflies of the genus *Hypolimnas*, Hübner. By means of a series of beautifully coloured lantern slides, he showed the changes in mimetic forms in a single genus of Nymphalid butterflies, from India through Arabia to Africa, and from India through the Malay Archipelago to Australia, commenting upon the resemblance they always bear in colour and pattern to different forms of *Danaïs* and *Euplœa*, insects well known to be distasteful to birds and reptiles.—Mr. G. F. Scott Elliot communicated a paper entitled "A revision of the genus *Pentas*," in which some account was given of the distribution of these plants in Africa, with a rectification of the synonymy, and descriptions of five new species. The genus as a whole showed in a remarkable manner the way in which local species occur whenever a different climate restricts the distribution of a wide-ranging form, and several examples of this were mentioned. A discussion followed, in which the President and Mr. W. P. Hiern took part.—On behalf of Dr. A. G. Butler, an abstract was read of a paper on butterflies of the genus *Charaxes*, of which 159 species were recognised, nearly all of which are represented in the National collection. Five species—*Charaxes princeps*, *C. repetitus*, *C. layardi*, *C. fervens*, and *C. coniger*—were described as new.

PARIS.

Academy of Sciences, November 11.—M. Marey in the chair.—The following memoirs have been submitted to Committees: "Comparison of the French, English, and German races by means of mortality tables," by M. Delauney. A note concerning the weight of the atmosphere, by M. F. Delmas. "On the formation of curved refractors and reflectors by means of plane mirrors and transparent plane surfaces," by M. Moret de Montjou. "The defence of the vine against phylloxera," by M. Leroux (Tenès, Algeria). "A contribution to the study of ferments," by MM. G. Nivière and A. Hubert. "The Cartesian planimeter with tangential registration. A new mechanical integrator of great precision," by M. José Ruiz-Castizo.—On a problem concerning the determination of the integrals of an equation to the derived partials, by M. E. Goursat.—On the unicursal types of two dimensions, by M. Léon Autonne.—On the homogeneous differential linear equations of which the general integral is uniform, by M. G. Floquet.—On the construction of new magnetic maps of the globe, undertaken under the direction of the Bureau des Longitudes, by M. de Bernardières. Seven survey expeditions have been equipped with the most modern appliances, and sent, under competent observers, to ascertain accurately the magnetic elements at numerous stations, and an eighth will be started as soon as the necessary instruments are obtained. The observing stations are grouped broadly round the great oceans.—Some effects of the synodic revolution of the moon on the distribution of pressures in the season of summer, by M. A. Poincaré.—On the hardening of extra-hard steels, by M. F. Osmond. With steels containing 0·35 to about 1·3 per cent. of carbon there is a gradual increase of hardness with increase of carbon contents, beyond 1·3 per cent. the steel becomes softer. A description is given of the method of investigating the structure of steel by abrasion with a sewing needle and microscopic examination of the scratch, and it is shown that the structure thus investigated leads to the conclusion that hard steels consist of two interpenetrating types of steel, of which one is much harder than the other. The same conclusion may be drawn by examination of etching figures, using iodine tincture or dilute nitric acid for the attack.—On the silicides of nickel and cobalt, by M. Vigouroux. These compounds of silicon and nickel or cobalt are produced in similar ways to the chromium and iron silicides. They have the composition $SiNi_2$, $SiCo_2$. They have a steel-grey metallic appearance, a specific gravity of about 7·1, and are more fusible than either of the constituents. Their properties in relation to halogens, halogen acids, oxygen, alkalies, and potassium nitrate are given in detail.—On crystallised normal calcium chromite, by M. E. Dufau. At a sufficiently high temperature, chromic oxide combines directly with lime to give a chromite of the composition $CaO.Cr_2O_3$. This compound is stable at the highest temperatures. It forms prismatic needles of metallic lustre, transparent in thin crystals, and of a fine green colour. Its hardness is 6, and specific gravity 4·8 at 18°.—On the alcoholates, by M. H. Lescœur. Sodium ethoxide forms no stable alcoholate, sodium hydrate appears to give the compounds $NaOH.3C_2H_6O$ and $NaOH.C_2H_6O$.—On the properties of emulsin from mushrooms, by MM. Em. Bourquelot and H. Hérissey. Emulsin from different fungi of the mushroom type appears always to be the same, and it cannot be affirmed to differ from the emulsin of almonds.—Constancy of the freezing point of some liquids of the organism. Application to the analysis of milk, by M. J. Winter. The author establishes the isotonism of body-fluids, more particularly of milk and blood-serum. "These liquids are equimolecular, and their molecular concentration is the same among the diverse animal species examined." The constancy of the freezing point of milk may be used as a means of detecting adulteration with water. Blood-corpuscles, along with their other functions, serve the purpose of regulating the concentration of the blood serum.—On fermentations caused by Friedländer's pneumobacillus, by M. L. Grimbert. There exist two types of Friedländer's pneumobacillus which are morphologically alike, but differ in their fermentative action. The pneumobacillus studied by Frankland has no action on glycerol and dulcitol, whereas that from the Pasteur Institute attacks these substances.—On the direct fixation, by vegetable fibres, of certain metallic oxides, by M. A. Bonnet.—On the detached crystalline rocks, probably of Tertiary age, in the Briançon Alps, by M. P. Termier.

NEW SOUTH WALES.

Linnean Society, September 25.—Mr. Henry Deane, President, in the chair.—Notes on Cicadas, by W. W. Froggatt.—Description of a tree creeper presumably new, by C. W. De Vis, *Climacteris animosa*, n.sp. Several examples were obtained in clearings in the Mulga Scrubs, at Charleville.—On the dates of publication of the early volumes of the Society's Proceedings, by J. J. Fletcher.—The President exhibited a number of botanical specimens from the Tweed River.—Mr. Froggatt exhibited his collection of Sydney Cicadas.—Mr. Steel showed a Gecko (*Gehyra vorax*, Gir.) from the Rewa River, Fiji.—Mr. Fletcher showed some English humble bees, the defunct portion of a consignment from New Zealand, recently imported by the Department of Agriculture in the hope of the successful acclimatisation of the insects. Of the remainder, some were liberated in the Botanic Gardens, and some in the Society's arden.

BERLIN

Meteorological Society, October 15.—Prof. Hellmann, President, in the chair.—Dr. Kassner spoke on the influence of weather on the growth of sugar-beets. He had compared the beet-root crops in the provinces of Saxony and Silesia, with the temperatures, rainfall, and intensity of rain during fifteen years, for the yearly period from October 1 to September 30. The curves of temperature corresponded to those of the crops in both provinces, except in 1887. On the other hand, the curves of rainfall in Silesia showed no such correspondence, although they were in somewhat greater harmony in Saxony. The curves of intensity of rain were in somewhat closer accordance with those of the crops, than were the curves of rainfall. The speaker came to the conclusion that the relationship of weather to crops requires a much more thorough investigation than is possible with the scanty data as yet available.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 21.

ROYAL SOCIETY, at 4.30.—(1) On the Gases obtained from the Mineral Eliasite. (2) On the New Gases obtained from Uraninite. Sixth Note. (3) On the Variable Stars of the δ Cephei Class: J. Norman Lockyer, C.B., F.R.S.—Microscopic and Systematic Study of Madreporarian Types of Corals: Miss Maria M. Ogilvie.—On the Calibrationof the Capillary Electrometer: G. J. Burch.—An Experimental Investigation of the Laws of Attrition: F. T. Trouton.—Experiments on Fluid Viscosity: A. Mallock.

LINNEAN SOCIETY, at 8.—Development of a Single Seed in the Fruit of the Cocoanut Palm (Cocos nucifera): D. Morris, C.M.G.—Assimilation in Plants under Abnormal Conditions: A. J. Ewart.—On a New Species of Pinites from Wealden (England): A. C. Seward.

CHEMICAL SOCIETY, at 8.—The Evolution of Carbon Monoxide by Alkaline Pyrogallol Solution during Absorption of Oxygen: Prof. Clowes.—The Composition of the Limiting Explosive Mixtures of various Combustible Gases with Air: Prof. Clowes.—Barium Butyrate and the Estimation of Butyric Acid: W. H. Willcox.—And other Papers.

LONDON INSTITUTION, at 6.—Relation of Ants to Plants: Prof. F. E. Weiss.

CAMERA CLUB, at 8.15—Mechanical Carriages: J. H. Knight.

SOCIETY OF ANTIQUARIES, at 8.30.

NUMISMATIC SOCIETY, at 7.

FRIDAY, NOVEMBER 22.

PHYSICAL SOCIETY, at 5.—An Exhibition of Photographs of Spectra: G. Johnstone Stoney.—A Direct Reading Platinum Thermometer: R. Appleyard.—Historical Note on Resistance and its Change with Temperature: R. Appleyard.

CLINICAL SOCIETY, at 8.30.

SATURDAY, NOVEMBER 23.

ROYAL BOTANIC SOCIETY, at 3.45.

MONDAY, NOVEMBER 25.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Faëroe Islands: Dr. Karl Grossmann.

INSTITUTE OF ACTUARIES, at 7.—Address by the President, Mr. Alex. J. Finlaison, C.B., on the Recent International Congress of Actuaries at Brussels.

MEDICAL SOCIETY, at 8.30.

CAMERA CLUB, at 8.15.—Daylight Enlarging: F. Seyton Scott.

TUESDAY, NOVEMBER 26.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Photo-ceramics. A Demonstration will be given by Mr. W. Ethelbert Henry.—A Method of Carbon-printing without Transfer: Valentine Blanchard.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion on Subaqueous Tunnelling by Shield and Compressed Air.

ROYAL VICTORIA HALL, at 8.30.—The Land of the Midnight Sun: Prof. Clowes.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, at 8.30.

WEDNESDAY, NOVEMBER 27.

SOCIETY OF ARTS, at 8.—Locomotive Carriages for Common Roads: H. H. Cunynghame.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

THURSDAY, NOVEMBER 28.

ROYAL SOCIETY, at 4.30 (Extra Meeting).—The following Papers will *probably* be read:—Mathematical Contributions to the Theory of Evolution. III. Regression, Heredity, and Panmixia: Prof. Karl Pearson.—The Expansion of Argon and of Helium as compared with that of Air and Hydrogen: J. P. Kuenen and W. W. Randall.—On the Percentage of Argon in Respired Air: A. Kellas.—Examination of Gases from certain Mineral Waters: A. Kellas and Prof. Ramsay, F.R.S.—On the Granular Leucocytes: G. L. Gulland.—On the Development of Lichenopora verrucaria, Fabr.: S. F. Harmer.

LONDON INSTITUTION, at 6.—A Forest Primeval: Prof. W. Boys Dawkins, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Electric Wiring Question: F. Bathurst.—Concentric Wiring: Sam Mavor.

SOCIETY OF ANTIQUARIES, at 8.30.

SATURDAY, NOVEMBER 30.

ROYAL SOCIETY, at 4.—Anniversary Meeting.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—British Birds' Nests: R. Kearton (Cassell).—Text-Book of the Embryology of Invertebrates: Drs. Korschelt and Heider, translated, Part 1 (Sonnenschein).—Royal Natural History, Vol. 4 (Warne).—A Laboratory Course in Experimental Physics: W. J. Loudon and J. C. McLennan (Macmillan).—Outlines of Psychology: Prof. O. Külpe, translated by Prof. E. B. Titchener (Sonnenschein).—Recettes de l'Electricien: E. Hospitalier (Paris, Masson).—Evolution in Art: Prof. A. C. Haddon (Scott).

PAMPHLETS.—Manchester Museum, Owens College, Museum Handbooks: Catalogue of the Hadfield Collection of Shells from the Loyalty Islands: J. C. Melvill and R. Standen (Manchester, Cornish).—The Ethnology of Buchan (Peterhead).

SERIALS.—Strand Magazine, November (Newnes).—Records of the Australian Museum, Vol. 2, No. 6 (Sydney).—Psychological Review, November (Macmillan).—Transactions of the Rochdale Literary and Scientific Society, Vol. 4 (Rochdale).—Journal of Conchology, January, April, July, October (Dulau).—Synoptical Flora of North America, Vol. 1, Part 1, Fasc. 1: Gray, Watson, and Robinson (Wesley).—Himmel und Erde, November (Berlin).—Royal Natural History, Part 25 (Warne).

THURSDAY NOVEMBER 28, 1895.

THE "TIMES" ON THE SCIENTIFIC SITUATION.

WE rejoice that at last the daily press is beginning to see the necessity of the State action which we have been preaching for some years to prevent as far as possible the ruining of many of our industries threatened by the development of scientific research and processes in other countries.

Yesterday the *Times* spoke out with no uncertain sound in connection with the often repeated cases in which, in various foreign markets, English are being replaced by German goods. The paragraph to which we refer runs as follows :—

"Our Berlin correspondent called attention two days ago to the immense strides made by German industry during the last quarter of a century, and to the failure of our Government to pay any adequate attention to a development so closely concerning British interests. In this commercial age this industrial nation has one commercial Attaché in Paris who is supposed to keep an eye upon all Europe, and one at St. Petersburg who has all Asia for his province. A commercial Attaché at Berlin for Germany alone would find ample occupation and would furnish knowledge of things that deeply concern us, which it may be feared neither the Government nor the mercantile classes of this country possess at present. We also require urgently a commercial Attaché with especial qualifications for the Far East. Yesterday our Paris correspondent informed us that on his first appearance as Minister for Foreign Affairs M. Berthelot asked money for the establishment of six new consulates in China. The contrast is sufficiently striking between the policy of the two countries, and the difference runs through the entire treatment of the material interests of the two peoples. Both in Germany and in France it is held an essential part of the duty of the State to second, and not only to second, but to stimulate and direct the efforts of private enterprise. In this country, though State interference with commerce is being carried to a dangerous length, State assistance, even in the way of collecting information, is regarded with stupid distrust and disfavour. Our home industries themselves in many cases languish for want of intelligent direction. Our agricultural distress might be alleviated were the State not far above the education of the population in the minor agricultural arts, and the organisation of agricultural industries after the manner in vogue on the Continent. In the same way, although nothing can excuse the short-sighted folly of our manufacturing classes in not providing for scientific research in the various branches of industry, yet it is the duty of a wise Government to take measures to counteract the folly of classes when it threatens the general interest. In one word, Great Britain stands at this moment in imminent danger of being beaten out of the most lucrative fields of commerce, simply because it does not recognise, while other nations do, the value of scientific organisation in the field, in the workshop, in the laboratory, and in the conduct of national policy."

The development of this question at the present moment, on the very day when the public meeting to promote a memorial to Huxley was held, reminds us how much we have lost—how much weaker we are for his absence. Never was Huxley more emphatic than when he pleaded, years ago, for the organisation of our scientific forces, so as to secure the victories of peace. It is now certain that we have lost many of these peaceful battles, and that we shall lose more, because our legislators have either not read the signs of the times, or have been led by those who, if they were consistent, would bring back our Navy to its state in Queen Elizabeth's time, when it was the outcome of individual and local effort.

It is encouraging to think that when the attention of the commercial classes has been drawn to what is happening, as it must be before long, and when the public will possess full knowledge of the utter chaos of our public departments in all things appealing to the national life, so far as it depends upon commercial enterprise under the existing conditions, some action must be taken. We have Committees of the Privy Council for this and that and the other departments, but where are the Scientific Privy Councillors? Where are the meetings held at which they give the State the benefit of their knowledge? In what record do we find the minutes of such "My Lords" as these?

It is not fair even to the administrators of the several departments that the present state of things should be allowed to exist. Too few of these have been chosen on account of their scientific knowledge, and as each question arises they have to pick up their information as best they can. There are several ways of doing this, one of them exhibited by the Board of Trade inquiry last week into the revised regulations referring to the Electric Lighting Acts. The Conference showed conclusively how much the Department gained by the free imparting of knowledge by outsiders.

But this is only one direction in which reforms are needed. The Chambers of Commerce throughout the country must sooner or later take the matter up; and when this is done, many other ways of abolishing the existing chaos will suggest themselves. Some of them we may refer to on a subsequent occasion.

EARTH-WORMS AND STREAM-WORMS.

A Monograph of the Order of Oligochæta. By F. E. Beddard, M.A., F.R.S. Pp. 769, 5 plates, and woodcuts. (Oxford: Clarendon Press, 1895.)

IT seems, at first sight, somewhat curious that such common animals as earthworms, occurring as they do all over the globe, should have received so little attention from zoologists until recent years: yet the neglect is not really to be wondered at, for earthworms are very much alike, and are only distinguishable from one another with difficulty even by a zoologist, while to the non-scientific traveller, collector or settler—to whom students of other classes of animals owe so great a debt—earthworms present no attractive character of form, and rarely of colour. Their subterranean habits, too, protect even brilliantly coloured, or specially large, species from the keen eye of the collector. Some of these worms reach a length of four feet, others are less than an inch; whilst most are uninterestingly coloured, there are some bright ones. *Megascolex cæruleus* is a beautiful peacock blue, *Microchæta rappi* is olive green, and pink below.

Notwithstanding their general unattractiveness, it might have been expected, however, that professional zoologists would have been acquainted with the anatomy of foreign earthworms long before the Franco-Prussian war; yet the first description of the internal organisation of a worm, recognised as being different from our European earthworms, only dates from 1868. About the time of this war, M. Perrier was preparing an account of the anatomy of nine new genera from various parts of the world, which were in the museum at Paris. After the publication of this memoir, in 1872, we have a gap of more than ten years, ere the number of foreign genera was increased; then, in 1883, Mr. Beddard described *Typhæus* from India. But from 1880 onwards, a constantly increasing number of contributions to the anatomy of the group has been published, so that, while in 1884 the bibliography in Prof. Vejdovsky's valuable monograph contains 283 references, that just published by Mr. Beddard refers to more than 650 memoirs.

In the handsome monograph under notice, Mr. Beddard treats his subject in a different manner from that followed by the Bohemian naturalist, who, to a very great extent, confined himself to those species which had come under his own observation. The present author, however, while bringing together facts collected by himself during the past fifteen years, deals fully with the researches of other zoologists. Vejdovsky paid more special attention to the aquatic forms; Beddard gives an adequate account of the entire group of Oligochæta. His work opens with a clear and excellent account of the general anatomy of the group, an account not overburdened with unnecessary detail, but yet containing discussions on many important points of morphology. This chapter should be of the greatest value to the general zoologist, who has long been in need of such an authoritative summary; for the group usually receives but scant attention from him, as after a detailed account of the anatomy and development of the British earthworm (to which, by-the-by, he frequently gives a wrong name), he leaves the rest of the earthworms as if they were not. Yet at least seventy-five genera of earthworms are known, some of which contain 100 species; and even in Britain we have as many as sixteen species, belonging to four genera.

In this anatomical chapter the author gives a very detailed and comparative account of the structure usually known as "prostate" or "atrium," which is generally connected with the end of the sperm duct; he suggests the term "spermiducal gland," which is in every way a useful and distinctive name. These structures have already received discussion at the hands of himself and others, and in the present book he essentially agrees with a view put forward by myself some time ago, though he misunderstands my views as to the Eudrilidæ. He is wrong in his statement that there is no peritoneum surrounding the "cement gland" of Tulificids, for I have figured this in the case of *Heterochæta*. He adopts the view, in which I quite agree, that the spermiducal glands have been derived from structures, such as occur in *Microchæta* and *Kynotus*, entirely independent of the sperm duct, with which they have, in most cases, become secondarily connected.

The monograph, unlike Vejdovsky's, gives a diagnosis of every known species of Oligochæta, both aquatic and terrestrial, which has been described in sufficiently recognisable terms; consequently, the book is invaluable to the specialist and to museum curators. The only member of the class which we miss is that peculiar leech-like parasite on the gills of crayfish, *Branchiobdella*. This has long been recognised as an Oligochæte, and it is not clear why Mr. Beddard has omitted it.

The chapter dealing with the classification and phylogeny of the group contains much that is of interest, and is by no means the "dry bones" that a systematic work frequently is. The class is divided into three "groups" of equal value (1): the Aphanoneura, for the genus *Æolosoma*; (2) the Microdrili, or aquatic worms and Moniligastridæ; (3) the Megadrili, or earthworms. Each of the latter "groups" (to which he does not give a technical term) he divides into families, some of which are grouped to form "superfamilies." But I cannot altogether agree with him in this primary subdivision. It is true that in 1890 (*Quart. Jour. Micr. Sci.*) I suggested the terms, Megadrili and Microdrili, much in the same sense as he uses them; but more recently I have been led to adopt Vejdovsky's opinion, viz. that all earthworms (except *Moniligaster*) form one family, and are to be contrasted with each (not all) of the families of water-worms. Beddard endeavours (on pp. 158 and 171), rather laboriously, it seems to me, to define these two "groups," but the Moniligastridæ have always been a stumbling-block, and Prof. A. G. Bourne's recent memoir (*Quart. Jour. Micr. Sci.* xxxvi.) tends to emphasise rather than to diminish the difficulty; for the clitellum of *Moniligaster*, on which Beddard lays much stress, is there described as being quite like that of an earthworm, and not like that of a water-worm.

Mr. Beddard's careful analysis of the affinities of the various families to one another, and, in later chapters, of the inter-relations of the genera, is a distinctive feature of this monograph, and he calls to his aid the facts from geographical distribution to support his contention that the Perichætidæ are the most archaic earthworms. The primitive arrangement of the bristles in earthworms was,

according to him, a circle round each segment; by reduction, the more usual number, eight, has been brought about. He refers to *Anisochæta* (which, by-the-by, we find on turning to the systematic part of the work, only a synonym for *Megascolex* sp.), a perichæte with only eight bristles on the anterior segments, as a step in this process, which in certain normal octochætous forms, may go so far as to cause the entire disappearance of bristles from the anterior segments. Since the monograph was in press, Prof. Bourne has published (*Quart. Journ. Micr. Sc.* xxxvi.) an account of the development of the bristles in the embryo of *Perichæta*, which rather tends to support the view, that the primitive number was eight, and that the perichætous condition is due to the appearance of additional bristles; and the fact that a circle of bristles occurs in another family of earthworms, as well as in certain Polychætes, also makes against Beddard's views.

Another phylogenetic point of special interest is that of the nephridia. Beddard and others have held that the "plectonephric" or "micronephric" condition is antecedent to the "meganephric"; but the ontogeny of three distinct genera contradicts this view, which Beddard, evidently with reluctance, now gives up. I quite agree with him and others, that my group "Plectonephrica" is artificial.

But while regarding the perichætous condition as archaic amongst earthworms, he places at the base of the whole Oligochæte tree (p. 173) a genus, *Phreoryctes*, in which there are usually only *four* bristles in each segment. Mr. Beddard recognises the difficulty of his position, but does not meet it in a very convincing manner. The facts of the geographical distribution of the earthworms are of great general importance, for the worms and their cocoons will not withstand prolonged immersion in sea-water, and modes of transference are few; the cocoons, being buried deep in the earth, are not likely to be carried on the feet of birds. "The characteristic earthworms of New Zealand are Acanthodrilids; the same family is equally characteristic of Patagonia and the adjacent islands; the only known earthworms from Marion and Kerguelen islands belong to the genus *Acanthodrilus*. These facts seem to me to be sufficiently important to require the formation of an antarctic region circumpolar in extent"—though it would not necessarily include the Cape. Australia is more closely allied to the oriental region (p. 154) than one would have suspected.

We may heartily congratulate Mr. Beddard on this able and readable monograph which he has found time to write, in addition to publishing many papers on other subjects in connection with his work as Prosector to the Zoological Society; and we may also offer our thanks to the Clarendon Press for undertaking this work. The book consists of 725 quarto pages of text, together with 85 pages of bibliography, and a full index (from which, however, we miss *Anteus*); there are five lithographed plates, and numerous illustrations in the text; it is well printed, with wide margins, and simply but effectively bound. But, while offering our congratulations, we must also record a grumble; for there are one or two omissions which detract from the usefulness of the work, from a systematist's point of view. (1) A tabular statement of the classification adopted, would have rendered his views more clearly and more readily than having to weed it out of the text: (2) a synopsis of differential family characters in tabular form, such as we find in the recent Catalogues of the British Museum, would enable one to refer an earthworm to its family with comparative ease. Tables of generic characters there frequently are; but they are often so ill-arranged as to be of comparatively little use. Some of these tables extend across two entire pages of fifty lines or more, and it is extremely difficult for the eye to follow these lines across the wide margins of the two pages (pp. 532–533), especially when, as in p. 632 of my copy, the pages are so bound that the lines do not correspond. This matter might have been so easily remedied by numbering the lines on each page.

Lists of the genera recognised as good, are usually given after the discussion of the family characters; but in some cases, as in Perichætidæ, the list does not appear.

The number of plates seems very inadequate to the text, and it is not evident what plan has been followed in selecting the species figured to illustrate the vascular system, for example; for not one of the figures pretends to give a complete plan of the system, and the chief types even are not represented. Plate v. will remain a mystery to many readers. The diagrams of the reproductive organs, which are on the plan adopted by me in my "Attempt to Classify Earthworms," might have been, with advantage, increased in number so as to include every family.

Such interesting matters as the encysted *Æolosom*, and the peculiarly modified genital setæ of Acanthodrilids, might well have been illustrated.

In such an extensive work as this, misprints and smaller errors can scarcely be excluded, but they are very rare; nevertheless, we think that all measurements should have been given in the metrical system. Here and there one finds "inches" cropping up (*Geoscolex maximus*); and sometimes, where the original measurements were in inches, the transformation to millimetres has been worked out wrongly (*Plagiochæta*).

But with all its faults, the monograph redounds to the credit both of the author and the publishers, and is a most welcome addition to our zoological standard works.

W. B. BENHAM.

DYNAMICS.

Dynamics. By P. G. Tait, M.A., Sec. R.S.E. Pp. 361. (London: Adam and Charles Black, 1895.)

THE main substance of Prof. Tait's present work has, for the past twelve years, been accessible to any one who cared to be at the trouble of consulting the cumbrous volumes of the "Encyclopædia Britannica," but we are glad that the author has at last been induced to issue his article on "Mechanics" in the form of a compact and handy octavo volume. This will be a useful addition to the library of every teacher who has to lecture to advanced classes, but the very encyclopædic treatment of the subject makes it rather hard to judge how far Prof. Tait's work meets the requirements of students. The author

himself says in the preface that "in teaching, I have found it advantageous to supplement the work at each stage by additional examples of the processes given in the text; as well as by references to special books in which particular questions are examined with greater detail." Considered as a synopsis of the principles of statics, particle and rigid dynamics, hydrodynamics, and even portions of elasticity, the book may safely be recommended either to mathematical students, or to such students of physics or engineering as have undergone the necessary preliminary grounding in higher analytical methods.

In its new form, Prof. Tait's "Dynamics" might be not inaptly described as a "Thomson and Tait for Beginners," and in scope and plan it is not very different from Ziwet's American treatise on "Theoretical Mechanics." It opens with a short introductory chapter on Newton's laws, followed in chapter ii. by over 80 pages devoted to pure kinematics, under which heading the analysis of strain receives a fair share of attention. Chapter iii. opens with a few further definitions relating to the laws of motion, chiefly extracted from "Thomson and Tait," followed by an outline of statics of a particle and the theory of attractions, including Green's theorem and the method of electrical images; the whole being condensed into 36 pages. Chapters iv. and v. deal with particle kinetics, and include 14 pages on the principle of least and varying action, and 6 pages on Lagrange's generalised equations. Statics and kinetics of a rigid body follow next, then a short chapter on the dynamics of a chain, in which vibrations of strings occupy only 7 pages. After this comes a still shorter chapter containing a few of the simpler applications of the theory of elasticity. In chapter x. the fundamental equations of hydrodynamics are disposed of in 25 pages, and are followed by a chapter on waves, based on Prof. Tait's "Encyclopædia" article on the subject. The author concludes with a short philosophical discussion on the "objectivity of force."

Unlike the ordinary run of text-books, this one contains no collections of examples, but in most of the worked-out problems, only the main results are stated, so that the reader will find plenty of work to do in filling up the gaps. Perhaps this plan will afford as good or better training than the usual routine of "bookwork and riders." There is a further advantage in the elimination of unnecessary formulæ from the text. The judicious use of small type has also done much in making the mathematical portion appear less formidable, and the use of dark type has been avoided by adopting the method of indention.

A reviewer naturally turns his attention sooner or later to the sections which deal with the laws of motion, and these cannot be said to be above criticism. The recognition of Newton's scholium to the third law as a separate dynamical principle is good, but we should have been glad to have seen greater definiteness in dealing with the second law. We all know that "quantity of motion" is to be interpreted as momentum, but Newton makes no mention of *time* in his statement, and modern text-book writers have remedied the deficiency by restating the second law in the following three different ways:

(1) *Rate of* change of momentum is proportional to the force.

(2) Change of momentum *in a given time* is proportional to the force. (In other words, change of momentum varies as the force when the time is kept constant; the fact that it varies as the time when the force is kept constant, being regarded as too obvious to require stating as a law.)

(3) Change of momentum is proportional to the *impulse* of the force, *impulse* being defined as the time-integral of a force.

Now, Prof. Tait appears to regard the law from the second standpoint on page 8, and from the first on page 100, and yet reference to the "Principia" suggests that the third interpretation is the most strictly Newtonian, since Newton evidently regarded *force* as capable either of being impressed gradually, or of being concentrated about a single instant of time. A statement of Prof. Tait's real views would have been far more acceptable than the series of definitions of "change of momentum," "rate of change of momentum," "rate of change of kinetic energy," "space-rate of change of it," with which chapter iii. opens. If a *rate* had been defined generally, these definitions would be superfluous.

In § 118 we are told that "the second law gives us the means of measuring force, and also of measuring the mass of a body." We had always thought (and still think) that the *third* law is required before *both* force and mass can be measured. For in comparing two forces, Prof. Tait supposes them applied in turn to the same body. But this test affords no criterion of the equality of two forces when applied to different bodies, as they have to be in comparing the masses of the bodies. If we assume an independent definition of equal forces (as, for instance, in Prof. Tait's illustration on p. 111, where he assumes that the same locomotive exerts approximately the same pull on two different trains), the second law, of course, affords a means of comparing two masses, but not otherwise.

We are sorry that Prof. Tait has not altogether banished from his book that highly misleading and artificial phraseology of "a point having several simultaneous velocities" in connection with the parallelogram law (§ 117). Combined with the definition of *velocity* as "rate of change of position," this always *seems* to suggest the (absurd) notion that the point moves into, and therefore occupies, different positions at the same instant. All that the parallelogram of velocities really proves, and what Prof. Tait proves in §§ 30, 31, is that if the velocity of A relative to B and the velocity of B relative to C are represented by two sides of a parallelogram, the diagonal represents the velocity of A relative to C. In passing from this to the parallelogram of forces, the discontinuity of reasoning could perhaps be overcome by a reference to Newton's commentary on his second law, which states that the effect of several forces is the same whether they be impressed simultaneously or successively.

In § 108 the author defines as "the 'component' of a force in any direction" what is now, with great advantage, usually called the *resolved part* of the force in that direction.

We should also like to see the use of the word "stress" avoided in connection with Newton's third law (§§ 174, 352), until some definite understanding has been arrived at as to whether the term is to signify a force, or (like

pressure) a quantity of the dimensions of force divided by area; but, after all, we have had to put up with ambiguities of this kind for so long, that the matter is of no great consequence to the class of readers for whom Prof. Tait's useful little book is intended. G. H. B.

OUR BOOK SHELF.

The People of the Moon. By Tremlett Carter. Pp. 402. (London: The *Electrician* Printing and Publishing Co., Ltd., 1895.)

THIS remarkable book bears upon every page evidence of scientific knowledge and vivid imagination. It is not simply a story of a journey to our satellite—that idea has been worn to threads since Jules Verne used it for the ground-plan of his novel—but purports to be a translation of a volume written by a lunar inhabitant, and sent to the earth. More than one ingenious individual has sapiently suggested that the side of the moon remote from us is inhabited; and as we are not likely to obtain any information on the matter, every one is free to indulge in that belief. The idea that there are living beings in the moon's interior, is of a similar harmless character, and the author of this book has made the most of it.

Down in the interior of the moon, and near the centre, dwelt a race of people—the Sarâva—who believed that the universe was an illimitable extent of solid rock, honeycombed throughout with endless tunnels and caverns. But a man arose—a lunar Copernicus—who propounded the doctrine that the place which the Sarâva occupied was merely a lump of cavern-hollowed rock suspended in an infinite vacant space. Urged by a vision, a Prince of the Sarâva sets out with two companions in the hope of reaching the surface, and their expedition is successful. With the adventures of the explorers, we have nothing to do, nor is it for us to analyse the sentimental undercurrent. The attractive parts of the story, from the scientific point of view, are those which show the author's acquaintance with electromagnetic waves and the ether. He makes the Sarâva possess machines to etherealise matter, so that by having two powerful electromagnetic foci at any distance apart, it was possible to transmit objects or people from one to the other with the velocity of light; the object being etherealised at one focus, projected to the other, and then by a similar series of electromagnetic waves converted into its material state. Having reached such a high state of knowledge of the ether, it is hardly necessary to say that the Sarâva could see and speak with one another at a distance, without the necessity of connecting wires, and had also managed to tap the ether and use its terrific energies in destructive weapons. How very intelligently, and with what regard to known facts these imaginary machines are constructed, can only be appreciated by a perusal of the book. We congratulate the author on the skilful and original way in which he has handled an old subject.

Frail Children of the Air. Excursions into the World of Butterflies. By Samuel Hubbard Scudder. Pp. 279. Nine plain plates. (Boston and New York: Houghton, Mifflin, and Co. London: Gay and Bird, 1895.)

IT might be supposed from the title of this book, that it was wholly popular, and that entomologists would find little to attract their attention in it; but this would be a great error, for it is really a collection of thirty-one philosophical essays on butterfly and caterpillar life, reprinted, with additions and modifications, from Dr. Scudder's great work on the "Butterflies of New England." Many subjects of great interest and importance are touched upon, relative to the modes of protection of butterflies in all their stages: fossil butterflies; the origin of the present butterfly fauna of North America; the habits of butterflies, caterpillars, &c. One of the most interesting chapters is, perhaps, that relating to the butterfly fauna of the White Mountains of New Hampshire, where butterflies appear to swarm to an extent which the richest localities in Europe could perhaps hardly parallel in number of individuals. Dr. Scudder does not confine his remarks to American species, however, but has also looked up the European literature bearing on his subject very thoroughly, as, indeed, was only to be expected from an entomologist of his industry and energy. Here and there, however, we may detect a casual oversight, as where *Iphiclides podalirius*, L., is spoken of as "confined to the Mediterranean region" (p. 247), when it is really found throughout the greater part of Central Europe as well. Occasionally, too, Dr. Scudder's information can be supplemented, as when in speaking of ants attending the larvæ of *Lycænidæ*, he omits the instances which have been recorded of some Australian species (*Hypochrysops delicia*, Hewitson, and *Ialmenus evagoras*, Donovan, &c., see Anderson and Spry's "Victorian Butterflies," pp. 94, 98, 99). Incidentally various subjects of more general interest are remarked upon, as where Dr. Scudder agrees with Desor (p. 250) in attributing the greater intensity, both of butterfly and of human life in America, as compared to Europe, to the much greater vicissitudes of climate in the former country; or when, in more than one passage, he agrees with Wallace and others, among our deeper-thinking naturalists, that the workings of natural selection are incomprehensible unless we regard them as guided by a controlling intelligence. W. F. K.

The Story of the Earth in Past Ages. By Prof. H. G. Seeley, F.R.S. Pp. 196. (London: George Newnes, Ltd., 1895.)

PROF. SEELEY tells the geological story of the earth in an orderly, though not strikingly luminous, manner. Beginning with evidence of the earth's internal heat, he passes to the materials of mountain chains, and then to the consideration of volcanic rocks. With reference to the latter section, it seems to us that his descriptions of the compositions of rhyolites, trachytes, andesites, and basalts are more suitable for a text-book than for a book intended for popular reading. In fact, Prof. Seeley has too exalted an idea of the knowledge of the general public, who, we are afraid, will not be able to understand a large part of his little book. Few of his unscientific readers will have any idea conveyed to them by remarks such as follow: "The bivalve shells are usually species of *Cyclas*, or *Unio*, or *Anodonta*. The univalve shells are either the pond shells *Planorbis*, *Paludina*, and *Limnæa*, or such river shells as *Neritina*, and the freshwater limpet." Similar instances of the use of technical nomenclature without explanation could be quoted from almost every chapter in the book.

The materials of stratified rocks form the subject of the fourth chapter, and then, after short descriptions of the succession of strata, the origin of stratigraphical geology, and fossils, the formations are treated in order, from the Archæan rocks to glacial deposits and gravel beds. Within the compass of less than two hundred small pages, it has only been possible for Prof. Seeley to indicate a few of the features of the different rocks. Thus, the chapter on Archæan rocks consists of three small pages, and would only fill about a column of NATURE, and there are other chapters just as scanty. Most of the figures are very badly reproduced, and there is no index; so that, altogether, we do not regard the book as a very satisfactory one.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Remarkable Sounds.

IN a book that was popular about fifty years ago, entitled "Journal of a Naturalist," the author says that the purely rural, little noticed, and, indeed, local occurrence, called by the country people "hummings in the air," was annually to be heard in fields near his dwelling. "About the middle of the day, perhaps from twelve o'clock till two, on a few calm sultry days in July, we occasionally hear, when in particular places, the humming of apparently a large swarm of bees. It is generally in some spacious open spot that this murmuring first attracts our attention. As we move onwards the sound becomes fainter, and by degrees is no longer audible." The sound is attributed to insects, although they are invisible.

A writer in the *Edinburgh Philosophical Journal* objects to this sound being attributed to insects, first because the fact is stated as being local and partial, heard only in one or two fields, at particular times of the year when the air is calm and sultry. He has often heard a similar humming in a thick wood, when the air is calm, and has diligently searched for insects, but in no case was able to detect them in numbers sufficient to account for the sound.

The same writer refers to remarkable sounds heard in a range of hills in Cheshire. When the wind is easterly, and nearly calm on the flats, a hollow moaning sound is heard, popularly termed the "soughing of the wind," which Sir Walter Scott, in his glossary to "Guy Mannering," interprets as a hollow blast or whisper. The explanation seems to be that a breeze, not perceptible in the flat country, sweeps from the summit of the hills, and acts the part of a blower on the sinuosities or hollows, which thus respond to the draught of air like enormous organ-pipes, and become for the time wind instruments on a gigantic scale.[1]

The greater intensity of sounds by night is ascribed by Humboldt to the presence of the sun acting on their propagation, by opposing them with currents of air of different density, and partial undulations of the atmosphere, caused by unequally heating different parts of the earth. In these cases, where the air suddenly changes in density, the vibrations which produce the sounds are divided into two waves, and a sort of acoustic mirage is produced in the same manner as a luminous mirage takes place from a similar cause. But there are, probably, other causes connected with the presence or absence, excess or diminution of solar heat, of moisture, &c., which may operate both in the increase or continuance of sound; while many peculiarities of place or season may create or modify certain sounds, which being local, admit only of special explanation.

The distances to which sounds sometimes travel are remarkable. Dr. Clarke, the traveller, states that, while 100 miles from the Egyptian coast, he heard firing therefrom, the air being very still at the time. Dr. Arnott mentions a case in which bells were heard at a similar distance by a ship off the coast of Brazil.

In Madame de Sévigné's gardens at Les Roches, near the town of Vitré, details have been given of an echo of so wonderfully multiplied a character, that rather than describe them, I prefer to ask for further information.

In another book, popular half a century ago, namely, "Forest Scenes," by Major Head, there is a description of sounds emitted by a sheet of ice fifteen or sixteen square miles in area, and three feet thick, when acted on by the wind. "A dreary undulating sound wandered from point to point, perplexing the mind to imagine whence it came, or whither it went, and whether aërial or subterranean, sometimes like low moaning, then swelling into a deep-toned note, as produced by some æolian instrument."

C. TOMLINSON.

The Story of the "Wandering Jew."

So far as my scanty reading goes, I have never met with a book on the subject of the "Wandering Jew" making mention of an Indian tale in this connection, and I therefore deem it more or less useful to call attention of the folk-lorists to the following Buddhist narrative, for which I have to thank Mr. Seisaku Murayama, an assiduous Pâli scholar in Japan, who was kind enough to make a journey in my behalf with the sole intention of personal examination of the Chinese text. The passage occurs in "Tsah-ö-han-King" (Sa*m*yuktâgama-sûtra, translated by Gu*n*abhadra, *circa* A.D 435–443), printed in Fuh-chau, 1609, tom. xxiii. fol. 30, and may be translated thus:—[This is a portion of an answer of Pin-tau-lu (= Pi*n*dola Bharadvâga ?) to the question of the King As'ôka.] "And further, when the Buddha was staying in the kingdom of S'râvasti with the five hundred arhats, the daughter of the *S*resh*th*in Anâthapi*n*dada happened to live in the kingdom of Fu-lau-na-poh-to-na (= Pundara-varddhana ?), and invited thither the Buddha and the monks. All other monks then, went gliding through the air; but I, exerting my supernatural energy, held up a huge mount and there went. Then the Buddha accused me with these words: 'Wherefore do you play such a miracle? for which offence I now punish you with eternal existence in this world, incapable of the reach to Nirvâ*n*a, thus to guard my doctrine against its destruction.'"

Dr. Baur and the Galapagos.

IN my article on Dr. Baur's botanical collections from the Galapagos (NATURE, vol. lii. p. 623), I stated that he was attached to the U.S. Fish Commission steamer *Albatross*. This was an error. Dr. Baur's trip was quite independent of Government aid, and was accomplished mainly through the liberality of two or three private gentlemen. So far as I can learn, there are no botanical results worth mentioning of the United States Government expedition.

I may add that Dr. Baur informs me that he is planning another visit to the Galapagos group, when he hopes to explore the Revilla Gigedos, Clipperton, Cocos, and Malpelo Islands; but that it cannot be carried out for two or three years to come. The natural history of all these islands is still very imperfectly known. The naturalist of the expedition of H.M.S. *Sulphur* brought home specimens from Cocos Island, about fifty years ago, of a dozen or more flowering plants, indicating no special insular differentiation from common tropical American types.

W. BOTTING HEMSLEY.

A Bright Meteor.

WE have received the following letter through Mr. R. H Scott, F.R.S., Secretary of the Meteorological Council:—

On returning home from sending you my sunshine telegram, this evening (about 7 p.m.) I witnessed the most superb meteor of my lifetime. The best conception I can give of it is to ask you to imagine a gigantic iron bar stretching over, I should say, one-eighth of the whole sky, and glowing as the wire glows in the incandescent lamp. It was almost at the zenith, and came from the east-north-east to the west-south-west. The glow remained for certainly one second, if not more time, and then slowly changed through all the colours of the spectrum, before finally disappearing. I should imagine it was seen over a large extent, and more must be heard of it. I assure you I esteem myself most fortunate to have witnessed a spectacle more magnificent than any before observed by me, although I witnessed the display of November meteors in 1866.

Eastbourne, November 22. R. SHEWARD.

A Long Drought.

IN connection with Brückner's prediction of a dry period culminating at this time, and the letter of Prof. J. P. O'Reilly in NATURE of October 17, the following account of a general drought from a Boston newspaper of November 11, may prove of interest.

H. HELM CLAYTON.

Blue Hill Observatory, November 12.

"The long drought, which has caused so much inconvenience and damage this fall, seems to have prevailed all round the world, if not in every part of it. Europe has experienced it almost equally with this country, and in Australia it has been more severe than here. So great was the distress in New South Wales, that the Government appointed a Sunday in September as a day of prayer for rain, and special services in accord with the proclamation were held in all the churches of every denomination in Sydney and throughout the province. The drought occurred in the Antipodean spring, and greatly retarded planting operations, as well as doing great general damage. In many districts

the grass was literally burnt off the earth, and the mortality among stock was great. The railway trains carried supplies of water from lakes and rivers to all stricken points along the lines, selling it at the rate of twenty-five cents a thousand gallons. The water supply of many towns entirely failed, the inconvenience experienced was acute everywhere, and many agriculturists were ruined.

"All through our own South the drought has been remarkable in its length, and some odd situations have occurred. In Kentucky the beds of many streams that have never before been dry are now full of dust, the mud having become baked hard, and then broken by the wind. At Uniontown, Kentucky, the Ohio was so low that an old coal vein under the river-bed was worked, and thousands of bushels of coal were taken out. In many places along the Ohio, Mississippi, and other streams, old wrecks have been uncovered by the lowering of the water, and the residents along the banks have recovered lots of more or less valuable cargo and junk. At Milton, Kentucky, there is a large sandbar on which many a barge of coal has struck and foundered. This bar was entirely uncovered recently, and the people living near by went to work with ordinary field ploughs and turned up tons of coal. In Maine and other eastern States the drought has been severe. The ice crop promises to be short, because lots of lands have gone almost dry, and there is no water to freeze. These general conditions have existed all over the continent, and in the north-west the situation is as bad as in the east and south."

The Pressure of a Saturated Vapour as an Explicit Function of the Temperature.

IN NATURE (October 24), Mr. Donnan observed that the "Law of Diameters" in combination with any equation of state, such as Van der Waal's, which applies to the region of coexistence of liquid and vapour, supplies an (empirical) expression for the maximum pressure of a vapour at any temperature T in the form of an explicit function of this temperature and known constants.

Led by the same thought, I have found the equation for the vapour tension.

The "Law of Diameters," in combination with the law of Maxwell-Clausius and the equations:

$$\zeta_1 + \zeta_2 + \zeta' = 3\zeta_\kappa$$
$$\zeta_1\zeta_2\zeta' = \frac{p}{ac}$$

{ζ_1 = density of the liquid, ζ_2 = density of vapour, ζ' = density lying between ζ_1 and ζ_2 (labile state)}

gives me

$$p = \mu \frac{(T - T_0)^3\left(\frac{T_\kappa}{T_0} - \frac{T_0}{T_\kappa}\right)}{T^{\frac{3T_\kappa - 4T_0}{T_0}}}$$

{T_0 = temperature, at which the tension of vapour is nil.}
T_κ = critical temperature.

The method of Mr. Donnan gives:

$$p = 3p_\kappa e^{1 - \frac{T}{T_\kappa}} \left\{\frac{24}{27}\frac{T - T_0}{3T_\kappa - 2T_0 - T} - \frac{(T - T_0)^2}{(T_\kappa - T_0)^2}\right\}.$$

If the "Law of Diameters" were consistent with the equation of state, the formulæ would be the same. G. BAKKER.

Schiedam, Holland, October.

Metallic Resistance and Radiation.

A RESULT published by Dr. Aschkinass, to the effect that the electrical resistance of thin metallic sheets like tinfoil is affected by the impact of radiation (electric waves), is often quoted; but, so far as I know, it has not been confirmed. My own experience tends to disprove it; but if any one has succeeded in confirming it, perhaps they would give us the benefit of the information. It is easy, of course, to get spurious effects with bad joints, in accordance with the discovery of Branly; and I see in your "Notes" (p. 60) to-day, that a Japanese experimenter, Mr. Mizuno, is of the same opinion.

November 22. OLIVER J. LODGE.

"L'Arithmétique Amusante."

IN the review of the above book (NATURE, November 7), mention is made of the curious fact that $8 \times 123456789 + 9 = 987654321$. It may be of interest to point out that this is not an isolated numerical curiosity, but is, I find, one of a group of similar curiosities which are included in the following easily proved theorem.

If the number formed by writing down in ascending order beginning with unity the first n digits of any scale whose radix is r be multiplied by $r-2$, and n be added to the product, the result is equal to the number formed by writing down in descending order the last n digits of the scale beginning with the last. WILLIAM LUCAS.

MR. LUCAS's theorem is quite correct: the cases for $r = 10$ have been given by E. Lucas in his "Théorie des Nombres," i. p. 28, as well as (if I remember rightly) in the "Arithmétique Amusante." M. E. Lucas was probably acquainted with the general theorem; whether he published it, or whether it has ever been published, I cannot say. G. B. MATHEWS.

Upper Bangor, November 19.

The Society of Medical Phonographers.

THE address of Dr. Gowers on "the art of writing in relation to medical and scientific work," delivered to the Society of Medical Phonographers, which was mentioned in your issue of August 8, and was published in the *British Medical Journal* for October 7, has been reprinted by the Society. There are a few spare copies, and any scientific worker, who is interested in the subject, can obtain one by sending a penny stamp to Mr. Wm. Holmes, printer, Ulverston.

It may be of interest to state that the number of members of the Society is now 202. I shall be glad to know the name of any scientific worker who uses shorthand.

JAMES NEIL, Hon. Sec.

Warneford Asylum, Oxford, November 22.

THE ROYAL COMMISSION ON SECONDARY EDUCATION.

IT would be difficult to produce a document more typically English than this Report, dated August 13, 1895, of the Royal Commission appointed on March 2, 1894, "to consider what are the best methods of establishing a well-organised system of secondary education in England, taking into account existing deficiencies, and having regard to such local sources of revenue, from endowment or otherwise, as are available, or may be made available, for this purpose, and to make recommendations accordingly."

That our country does not possess even an approach to a system, let alone a *well-organised* system, of secondary education, is in itself a sufficiently remarkable circumstance; but some may think it even more remarkable that, having recognised this, a task so difficult as that before the Royal Commissioners should have been entrusted so recently as last year to persons who, however worthy individually, as a body but very imperfectly represent the vast interests involved in such an enquiry. More than a quarter of a century has now elapsed since the publication of the report of the Schools Enquiry Commission appointed in 1864, and in the interval science has not only advanced with giant strides, but has also been applied to industrial purposes to an extraordinary extent, with the result that a revolution has taken place affecting not only all our actions, but our very modes of thought also, and requiring us to take cognisance of many entirely novel conceptions and considerations. Meanwhile also, our national prosperity has received a most severe check through the competition of those who have been quicker than ourselves to avail themselves of scientific discoveries and methods of working; and the probability is great that such competition will rapidly increase in severity and become unbearable unless we, as Huxley said, "organise victory"—to do which, however, we must march very fast, as we have both to overtake those who are already far ahead of us, as well as go quickly when we come up with them. It was therefore imperative that in considering the organisation of

secondary education, we should fully take into account and avail ourselves of the teachings of science. And it is consequently just cause of complaint that only a single representative of science—Sir Henry Roscoe—should have been placed on the Commission.

NATURE may also well object to the limited construction put by the Commissioners upon the reference submitted to them—that they should have understood it to so confine their enquiries as to lead them to think that it was not their function to include either an examination and description of the instruction now actually given in secondary schools, or a consideration of what subjects it ought to cover, and by what methods it should be given; and that consequently they should have mainly restricted themselves to what they call the external or administrative part of the subject. This, to the ordinary mind, is not unlike leaving out of account the weapons used in modern warfare, as well as all questions of tactics, in considering the organisation of our defensive and offensive forces; as education must in the future be the arsenal in which our weapons both of defence and offence will be mainly fashioned, the parallel can scarcely be said to be wanting in appositeness. It is all the more remarkable that the Commissioners should have taken so narrow a view, as on the second page of the Report they say that the object they had before them was nothing less than to complete the educational system of England, now confessedly defective in that part which lies between the elementary schools and the Universities.

Among those who have studied the conditions of English education and compared it with the best foreign systems, who are aware of the state of English public feeling on such matters, and who also take into account the altered conditions under which we now live and work, the impression is strong, however, that nothing is more wanted here than a clear declaration of policy which would serve to form public opinion and lead it into the right direction as regards the character of education most suited to the times. Although confessedly a practical people, we continue to allow our children to receive an education bearing little relation to the practical needs of life; the reason being, probably, that we do not sufficiently recognise that we owe our success almost entirely to innate good qualities, and that Englishmen have been helped in a comparatively small degree in what they have done by their school training.

It should have been easily within the powers of the Commissioners to have properly discussed such questions, and it is surprising that it should have been found difficult "to secure the help of those who, while not directly or professionally connected with secondary schools, had studied educational problems." And besides hearing witnesses belonging to the class of "educational statesmen and thinkers," workers might perhaps have been listened to with even greater advantage—when the theoretical evidence tendered by some is contrasted with that of an accomplished and experienced worker like Miss Beale, for example, there is no difficulty in deciding which is the more valuable. If also the opinions of a few experienced instructors at the universities and elsewhere, who have to do with large numbers of average students from secondary schools, had been invited, material would have been accumulated of importance in determining our future educational policy, and which probably would have led the Commissioners to open their eyes very widely: information as to the previous places of education of undergraduates at the universities is of little use in comparison with information as to the quality of their attainments.

Not a single scientific witness was called! Yet, if among the memoranda on particular topics invited from persons believed capable of furnishing valuable data or views, memoranda on the place of science in education and the kind of teaching required had been invited, there would not only have been no difficulty in securing such, but the documents would have had a high value. The mere fact that technical education was included in the enquiry, and indeed occupied a very considerable share of attention, is in itself sufficient evidence of the necessity of taking such a subject into consideration. But the Commission was clearly so constituted that it could not appreciate the importance of such action being taken, composed as it was very largely of men who cannot be regarded as belonging to the modern school of educational thought. Consequently, and most unfortunately, it has contributed little, if anything, towards the understanding of the difference between true scientific teaching—not merely of science, but of all subjects—and the sham article with which this country has so long been flooded; the wearying fight to bring this home to all concerned must therefore be continued with unremitting vigour. And this is the more disappointing, as it is so clear that, had the Commissioners advanced but very little further, they could have helped us in this direction also; for how otherwise are we to interpret the following admirable conclusion to the summary appended to the second section of the Report, that relating to the present condition of secondary education in England?—"In every phase of secondary teaching, the first aim should be to educate the mind, and not merely to convey information. It is a fundamental fault, which pervades many parts of the teaching now given in England, that the subject (literary, scientific, or technical) is too often taught in such a manner that it has little or no educational value. The largest of the problems which concern the future of secondary education is how to secure, as far as possible, that in all schools and in every branch of study the pupils shall be not only instructed, but educated. The degree in which this object may be attained will be largely influenced by the action of the authorities who prescribe the qualifications to be required in teachers, the conditions under which their work is to be done, and the means by which their work is to be tested."

Surely it was the duty of the Commissioners to take the first step towards solving what is admitted by themselves to be the largest of the problems concerning the future of secondary education—it is not likely that another Commission will be appointed to do this!

The Franco-German War first drew the attention of the world to the extraordinary value of exact training and scientific organisation. The lesson was most taken to heart by the Germans themselves, and by carefully training the *officers* of their army of industrial workers, they have since come off victorious in many important engagements with rival manufacturers and traders. An almost deeper lesson has recently been given to the world by the Japanese. Unless *we* are prepared to entirely disregard such lessons, we must introduce drastic reforms into our whole system of education. Scientific ways of working—scientific habits of thought, must be made national habits. The change would be nothing like so absolute as that made by the Japanese in their system of working, and if such a nation could entirely alter its front, it should not be beyond our power to do what is so clearly essential to our continued existence in comfort, let alone prosperity.[1]

[1] I cannot refrain from quoting the following conclusion to a striking article on the "Far Eastern Question" in to-day's *Times* (November 27). "Although nothing can excuse the short-sighted folly of our manufacturing classes in not providing for scientific research in the various branches of industry, yet it is the duty of a wise Government to take measures to counteract the folly of classes when it threatens the general interest. In one word, Great Britain stands at this moment in imminent danger of being beaten out of the most lucrative fields of commerce, simply because it does not recognise, while other nations do, the value of scientific organisation in the field, in the workshop, in the laboratory, and in the conduct of national policy." The *Daily Telegraph* has recently published an interesting series of letters—"Lessons in German"—conveying a similar lesson. We have waited long for the daily press to assist us: such evidence that the gravity of the situation is at last attracting attention is therefore most valuable.

To have conveyed this lesson to the nation should have been the first duty of the Commission. It is difficult to discover a sentence in the Report which indicates that they appreciate the gravity of the situation in which we are placed! Englishmen require but to be led properly at starting—when once they understand what to do, they will help themselves. The extraordinary outburst of educational activity which the country has witnessed during the past twenty years is proof that we are not behind in our estimation of the value of training; but the amateur fashion in which a very large proportion of our new enterprises have been conducted, shows only too clearly that an ideal is wanted to guide our labours: if we had this, co-ordination of means would naturally follow. We realise, in fact, that our army must be drilled, but we want a new national drill-book, in which the tactics to be adopted are *broadly* indicated. The Commissioners have only advised us as to the construction of barracks, and the choice of a staff; still, if we follow their advice and not only choose our staff, the Minister and his Educational Council, wisely, but impose on the latter in the first instance the task of most carefully framing the outlines of a system of tactics, all may yet be well.

Whatever may be the shortcomings of the Report in these respects, all who study it must agree that it is a work of the very highest value, drawn up with great skill, and that the recommendations embodied in it merit the most serious consideration.

In addition to the Report, there are three volumes of minutes of the evidence tendered by eighty-five witnesses; a fifth volume contains memoranda and answers to Commissioners' questions; two others are devoted to the reports of Assistant Commissioners; and the remaining two contain a summary, an index and statistical tables.

As the Commissioners point out, a mastery of the details is essential to a comprehension of the problems they had to solve, and an appraisement of the solutions they offer. Perhaps those who can read between the lines may be inclined to draw inferences in some cases different from those arrived at by the Commission; and it is clear, also, that the evidence is not all equally trustworthy—at least one of the Assistant Commissioners' reports having called forth what appear to be just protests.

The opening section of the Report contains a very brief, but most instructive, historical sketch of the gradual development since 1867 of the various agencies which have induced progress; four are chiefly referred to: the Elementary Education Act of 1870, the Science and Art Department, the various new University Colleges and the women's colleges, and the Technical Instruction Act; the work accomplished by voluntary effort, and the great increase in public interest in educational matters being also specially mentioned. Most hopeful in tone, this section is sadly wanting in scale; while no distinction is made between the work done under the Science and Art Department and by the University Colleges, the reference to University Extension is of the roseate order usually made by its extreme advocates. It is unfortunate that no attempt to estimate the relative values of the different elements of our educational "system" is included in this or the following section.

The second section deals with the present condition of secondary education in England, under the three heads: authorities exercising control, the existing supply of secondary teaching, and bodies which examine or inspect. The problems which the survey suggests are then considered, and, among others, the defects are pointed out in the present system of science and art grants, in the supply of schools, and in the provision of scholarships; but, unfortunately, under this last heading no attempt is made to take fully into account the bad, as well as the good, effect on scholars and schools of scholarships: the subversive effect they have produced at our universities is so generally recognised by competent observers that this subject should have been carefully considered. In discussing the internal organisation of schools in this section, stress is laid on the need of training for secondary teachers. This, perhaps more than any other portion of the Report, requires most careful study in connection with the evidence, and remarks on it must be reserved for a future occasion. The measures to be taken in the training of teachers will undoubtedly be the most vital point in any future legislative action arising out of this Report; for given good teachers, good work will necessarily be done, whatever the conditions may be in other respects.

A most important paragraph occurs in the summary to this section, which will need to be very carefully discussed, viz. that "In organising the supply of schools, it will be of the utmost importance to provide adequately for the literary type of secondary education, no less than for the scientific and the technical." One question to be considered is whether there should not be a *mean* type instead of distinct types throughout all the earlier stages, at least, of secondary education. Unfortunately this issue seems never to have been presented to the Commission.

The third section, which is by far the longest, is devoted to a review of the evidence, and a discussion of the suggestions made by certain witnesses.

The fourth, and practically the most important, contains the recommendations which are unanimously brought forward by the Commissioners. The primary recommendation, to which probably most interest attaches, is that of a *Central Authority* calculated to bring the State into a fitting relation to secondary education—words deserving of special notice. The proposal made is essentially English in spirit, and thoroughly calculated to fall in with our belief in a decentralised system of local self-government giving the maximum opportunity to individuals. "So far from desiring that secondary education should be a matter for a department of State to control," say the Commissioners, "we propose to leave the initiative in public action to local authorities, and to prevent even those authorities from superseding the action of individuals. So far from attempting to induce uniformity, we trust that a free and spontaneous variety, and an open field for experiment and enterprise of all kinds, will be scrupulously observed. We conceive, in short, that some central authority is required, not in order to control, but rather to supervise the secondary education of the country, not to override or supersede local action, but to endeavour to bring about among the various agencies which provide that education a harmony and co-operation which are now wanting."

The Central Authority proposed is a Minister responsible to Parliament presiding over a department formed by merging into one body the present Education Department, the Science and Art Department, and the Charity Commissioners. Apart from other advantages, the appointment of a Minister of Education must have the effect of impressing on public attention the immense national importance of educational affairs; and much as we have been indebted in the past to the several departments which it is suggested should now be fused into one, their methods are too inelastic to suit modern needs, and the proposed change is probably one which will meet with the approval of all true friends of education.

It is further proposed to associate with the central authority an Educational Council, not exceeding twelve members, of whom one-third might be appointed by the Crown; one-third by the four universities of Oxford, Cambridge, London, and Victoria; whilst the remaining one-third might be co-opted from among experienced members of the teaching profession. This proposal will probably be viewed in very different ways, but it appears to be one which is eminently calculated to pre-

serve the educational freshness of the central authority, and limit within reasonable bounds the display by it of those peculiarities which are too frequently manifest in all official bodies; through such a body, the interest of the Minister, and through him of the country at large, in current educational problems would be awakened and maintained, and he would become fully open to influence from without; at the same time, it should minimise the tendency to subordinate educational to political interests. But to secure these ends, the Council must contain a large professional element, and its members must not in any case be mere men of affairs, but fully acquainted with educational requirements.

It is impossible now to discuss the remaining recommendations.

At the outset, the Commissioners state that they have felt very strongly the need of dispatch, in order that the country may without delay derive advantage from legislation framed on proper lines. It is to be supposed that the late Government would have acted promptly in the matter, and it is to be hoped that its successors will be at once ready to appreciate the vast importance to our nation of well-considered legislation in the direction of the scheme put forward by the Commissioners. It would probably be difficult to prepare one in which due provision is more fully made to conserve what is good in our present system, while permitting the fullest play to the agencies which determine progress.

To conclude, in the eloquent final words of the Report, "it is not merely in the interest of the material prosperity and intellectual activity of the nation, but no less in that of its happiness and its moral strength, that the extension and reorganisation of secondary education seem entitled to a place among the first subjects with which social legislation ought to deal."

HENRY E. ARMSTRONG.

PAGAN IRELAND.[1]

TO Colonel Wood-Martin is due the credit of the first attempt to co-ordinate the vast stores of archæological lore which lie buried in the publications of the various Irish societies. The subject is a really fine one, and it was time that the data of Irish archæology should be collated and presented in a convenient form. This the author has accomplished. There are two ways of regarding a book: the one is to expect the author to write the book in the way you (whoever "you" may happen to be) would like to have it written, and the other is the acceptance of the author's position, and to deal with the work from that point of view. It is not difficult to discover the ideals which the author has in this instance placed before himself. "In order to arrive at the truth, it is desirable to test the opinions and conclusions of those who, by a careful analysis of the probabilities and facts recorded by them, have travelled over the same ground before. . . . Antiquarian research in Ireland may, with advantage, be directed towards filling in the social history of primitive man; articles which are the result of the handiwork of the aborigines illustrate, with much exactitude, life in the olden days. . . . If material objects be accepted as proofs of the pagan ideas and customs of the aborigines, surely the evidence of still existent superstitious observances of the peasantry, which can be traced to a pre-Christian source, ought to be received with, at least, the same authority. . . . It is to be hoped that research into the past, on these lines, may contribute to the reconstruction of early history." This is a sound method of treating archæology; our author clearly recognises that the value of archæology, whether it be of objects made by man, or of folk-lore, lies in the use to which it can be put in deciphering the early history of man, and he admits that in Ireland "we have made but little progress in higher scientific archæology; and the ancient antiquities of Ireland still remain in an unclassified condition." This is a refreshing admission, and the justification of this statement is only too apparent to those who know the present unintelligent arrangement of the magnificent collections of the Royal Irish Academy, now housed in the Dublin Science and Art Museum. The splendid opportunities for archæological research which exist in Ireland, are woefully neglected, and it is to be hoped that Colonel Wood-Martin's book will serve to stimulate an interest in this fascinating and promising field of inquiry. We are glad to note that he refers to the "vandalism" of the Board of Works with regard to ancient monuments; but a great deal more has yet to be said on this subject.

FIG. 1.—Legananny Cromleac, Castlewellan, Co. Down, 10 feet in height. (From Welch's Irish views.)

In his chapters on "Early History," "The Disposal of the Dead—Were the Aborigines Cannibals?" and "Traces of the Elder Faiths," the author deals with customs and beliefs as recorded in ancient accounts, or as witnessed for by actual remains, or as perpetuated in an attenuated form in folk-custom. The facts here collected together are most interesting, and throw considerable light on the early social condition of Ireland, a good deal of which will be new to the ordinary reader.

The author is very weak in his account of the ethnology of ancient Ireland; but this is a matter in which the author, not being a professed anthropologist, is not so much to blame, and there is yet much investigation to be done before we can speak with certitude. At

[1] "Pagan Ireland, an Archæological Sketch. A Handbook of Irish Pre-Christian Antiquities." By W. G. Wood-Martin, M.R.I.A., author of "The Lake Dwellings of Ireland," "The Rude Stone Monuments of Ireland," &c. 689 pp., 410 figs., and map. (London: Longmans, Green, and Co., 1895.)

all events it is a pity to promulgate the statement that "the Esquimaux and cognate people appear to be all members of the most primitive family amongst

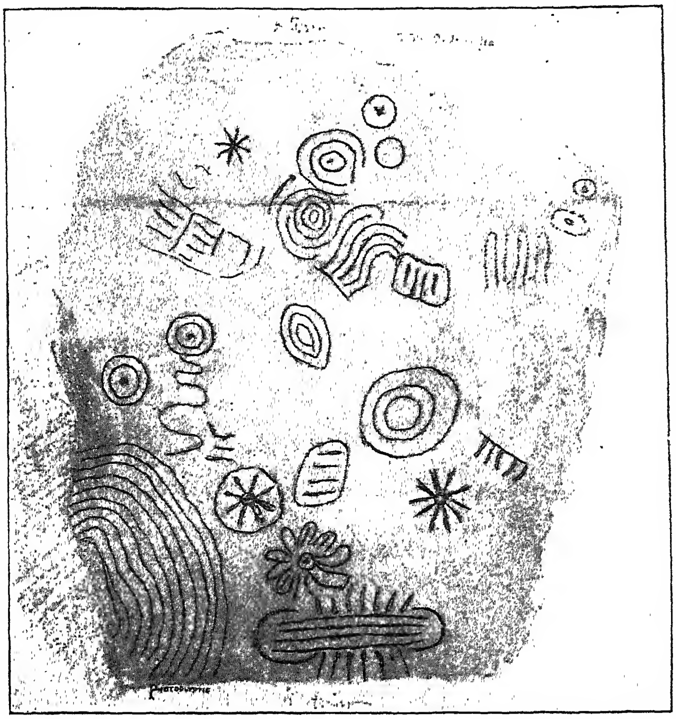

FIG. 2.—Inscribed Stone from a Carn on the Loughcrew Hills, Co. Meath.

the nations," and he adopts the view that the men of the period of the megaceros and the reindeer "approximated in type to that now inhabiting the Arctic regions." He is apparently unaware of the distinguishing cranial characters of the Lapps and Eskimo. While admitting that there is a culture analogy between the latter people and those of Neolithic times in the British Islands, there is no evidence for ascribing them to the same race. The figures of the skulls on p. 21 are ludicrously erroneous.

When Colonel Wood-Martin passes to the more well-beaten paths of archæology, there is less to criticise, and it is evident that he writes not only of facts gathered from a large range of reading, but also from wide personal knowledge. We have a satisfactory epitome of what is known on early domestic architecture in the shape of beehive huts, souterrains, cashels or forts, raths, and the like; as the author has made a special study of crannogs, the Irish lake-dwellings are adequately described. There is an interesting chapter containing a good deal of folklore on various rude stone monuments, including cromleacs, carns or tumuli, pillar-stones, holed-stones, &c. Clay vessels and stone urns have a chapter to themselves, and a number of them are figured. In dealing with stone implements we find this statement: "In the Palæolithic or ancient stone period, the manufacture of implements was so rude that it is difficult to distinguish between the flints artificially chipped by human agency, and those shaped by natural causes." As it stands this is very misleading, for the ordinary Palæolithic implement is as recognisable as the Neolithic.

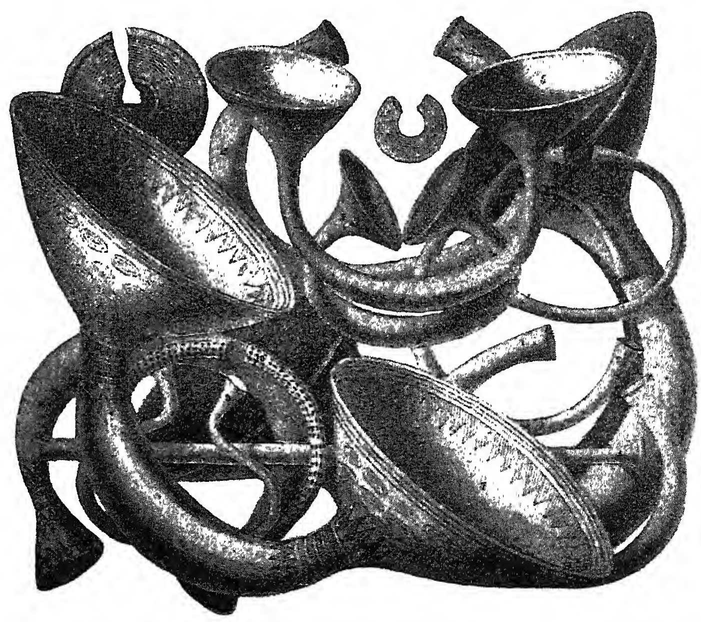

FIG. 3.—Group of miscellaneous Gold Ornaments (total value, £1000). Slightly less than one-half natural size.

A succinct account is given of the various kinds of stone arrow-heads, and of the bronze swords, daggers and spear-heads, and they are classified according to their several types; but we are not given any information as to their distribution, nor is any clue given as to their relative dates of the bronze weapons or of their foreign equivalents. The well-known story of the evolution of the socketed hatchet from the simple flat copper celt is, however, detailed. The famous gold ornaments are duly described, and from the number of ornaments in museums, especially in the Museum of the Royal Irish Academy, and from the records of finds, there is abundant evidence that Ireland was at one time very rich in that precious metal; indeed, it is probable that gold ornaments were an important article of trade, and we know that the Danes and other Scandinavians raided the country and rifled the tumuli and other tombs, being tempted by these valuables. During the present century, between £30,000 and £40,000 worth of gold ornaments are known to have been melted down.

A number of the mysterious rock-scribings are illustrated, but no fresh light is thrown upon them; indeed, the chapter on ornamentation is not so satisfactory as it might have been.

The book is well printed, copiously illustrated, carefully indexed, and one very valuable feature is the bibliography, which gives a classified list of over a thousand references.

To sum up: the author has aimed high, and has evidently spared no pains to do his best, and he has succeeded in producing a book which affords an extremely convenient introduction to Irish archæology; he has compiled diligently, but the exercise of more criticism, and of a broader way of regarding the data of archæology, would have resulted in a better book; despite his own ideals the author has not succeeded in getting, so to speak, outside his subject.

THE METRIC SYSTEM OF WEIGHTS AND MEASURES.

A DEPUTATION representing forty-six Chambers of Commerce, announced in these columns a fortnight ago, waited upon Mr. Balfour, First Lord of the Treasury, on November 20, to urge upon the Government the desirability of adopting the metric system of weights and measures, as recommended by the late Select Committee on the subject. It will be gratifying to men of science to know that the commercial world has been brought to support a reform advocated by them for many years. When the question was merely one of simplicity, little importance was attached to it, but now that commercial men have learned that our chaotic system of weights and measures is a serious obstacle to international trade, the matter is taken into the region of practical politics. On the whole, Mr. Balfour's reply to the deputation is satisfactory. The best way to the adoption of the metric system in this country is by educating the mass of the people in its use; in other words, the transition will have to be gradual rather than an abrupt change brought about by legal process. By all means let the metric system be legalised, but it cannot be seriously believed that in two years people would submit to having the system thrust upon them by Act of Parliament. The Select Committee of the House of Commons recommended "That the metrical system of weights and measures be taught in all public elementary schools as a necessary and integral part of arithmetic, and that decimals be introduced at an earlier period of the school curriculum than it is at present." This recommendation ought certainly to be carried out, for when the use of decimals has become common, and the convenience of the metric units has become widely known, there will be little need for legislation to make the use of the system compulsory. But the question is not only one of ways and means; for if England adopts the metric system, then France will, in all probability, adopt Greenwich time, and there will then be one time system throughout the world.

The deputation to Mr. Balfour was introduced by Sir A. K. Rollit, M.P., who was supported in his remarks by Sir Henry Roscoe, Sir Samuel Montague, M.P., Mr. Arnold-Forster, M.P., and several other members.

Sir Henry Roscoe said: As Chairman of the Select Committee, the report of which has been referred to in the memorial, I desire, Mr. Balfour, to be allowed to say a few words on the question at issue, of which, I may add, it is difficult to overestimate the importance; and, in the first place, I wish to remark that the Committee consisted of seventeen Members of Parliament, chosen from both sides of the House, and that of these seventeen only one was opposed to the recommendations made by the majority and embodied in the report—*i.e.* that the metrical system of weights and measures should be at once rendered legal for all purposes of trade as well as for manufacture; and that, further, within a space of two years, the metrical be adopted as the only legalised system. These recommendations were founded on the evidence given by thirty-two witnesses, representing very many different interests, and selected from persons of every class of the community. Of these only one—*i.e.* Sir Frederick Bramwell—was in favour of retaining the present system, although he had no objection to the legalisation of the metrical weights and measures. With this single exception all the witnesses expressed a very strong opinion as to the evil effects arising from the complicated and unsatisfactory condition of our present system of weights and measures. They called attention to the distinct and serious degree to which, in their opinion, our commerce—especially our foreign commerce—is handicapped in consequence of the use of the present system, differing, as it does, from that now adopted by every European nation except ourselves and Russia, as well as by far the greater majority of the non-European countries with which this kingdom trades. Not only, however, was it proved to the satisfaction of the Committee that our foreign trade suffers greatly, but also that our home trade would be benefited by the adoption of a simpler and uniform system of weights and measures.

From the educational side, also, evidence showed the urgent need of an adoption of a simpler system, and it appears from the statements of experts that the school time now devoted to arithmetic would be lessened by one year if a simpler system were substituted for the cumbrous one now in vogue, and thus our children placed on a par with those taught in foreign schools. This led to the second recommendation—viz. "That the metrical system be taught in all public elementary schools as a necessary and integral part of arithmetic, and that decimals be introduced at an earlier period of the school curriculum than is the case at present, and before vulgar fractions."

On inquiry, the Committee learnt that the compulsory changes from old and complicated to a new and simple system had been accomplished in Germany, in Norway and Sweden, in Switzerland, in Italy, in Bulgaria, in Japan, in Turkey, and even amongst the black population of French dependencies in Africa, without any difficulty in a comparatively short period of time, and without any opposition; that in every case the people in these countries are satisfied that the change has been for the better, and that in no single instance has an attempt been made to recur to the old system.

It has often been stated that this agitation for the adoption of the metrical system is got up by scientific men or faddists, who have no knowledge of the practical difficulties which will arise in the application of a new system to ordinary life. That this is not so is shown not only by the composition of the present deputation representing, as it does, so powerfully the commercial interests of the Empire, but also by the statement emphasised in the evidence given before the Committee, that the working classes, at any rate the more intelligent of them, are interesting themselves in the matter and have passed very strong resolutions in favour of the change. Thus the Trade Union Congress held in Glasgow in September 1892, at which 495 delegates were present, representing nearly a million and a quarter of members, passed the following resolution: "That in the opinion of this congress it is highly desirable in the interests of the working classes and of the general trade of the country that the decimal system (meaning the metrical system) of weights and measures shall be adopted in Great Britain and Ireland as a national system, and that a Parliamentary Committee be instructed to promote legislation on the question"; whilst a similar resolution was passed at the Belfast Congress in the following year, at which 380 delegates were present representing 900,000 members. A large number of other trade societies have sent in memorials in favour of the adoption of the metrical system; amongst many others, the United Bargemen and Watermen's Protection Society, the Working Men's Club and Institute Union, the Trades Councils of Sheffield, Glasgow and Bolton, the National Union of Gas-workers, the Boot and Shoe Union of Leicester, the Manchester and Salford Trades Council, the Dockers Union, the Amalgamated Society of Railway Servants in Scotland, and the General Railway Workers Union.

Important evidence was obtained from manufacturers who have adopted the metrical system in their works; the most interesting of these is perhaps that of Captain Sankey, a director of the well-known firm of Willans and Robinson, engineers. This firm has adopted the metrical measurements, not only to their own advantage, but to the satisfaction and with the cordial co-operation of their workmen, some of whom are merely ordinary English labourers. A series of questions was drawn up by the firm, for the purpose of ascertaining how far the men were satisfied or otherwise with the change, and the answers to a number of searching questions showed that the men were not only satisfied but pleased, and had no wish to recur to the old measurements. An honourable member of the Committee asked this witness whether he had found that his men had any difficulty in adapting themselves almost immediately to the new system, and the answer was, "Not after the first few days." The witness added: "I asked that very question to the head of our tool-room, and he said it was a little awkward for a time. I said, 'About how long?' and he said 'Two days.'" And in further examination this witness stated that the workmen knew nothing of the metrical system beforehand.

Another interesting witness was the Chairman of the Incorporated Society of Inspectors of Weights and Measures. He came forward as an expert in these matters, and he agreed that the metrical system ought to be made compulsory, and in expressing this opinion he spoke for his Society. He gave a long list of anomalous customary measures, which are now, although illegal, still in use

in various parts of the country. He explained that it was difficult, under the present system, to prevent the use of these irregular weights, but that if a new unit or system were adopted, then it would be possible to put an end to the employment of these ridiculous so-called customary weights.

The Committee found it impossible to obtain any evidence either from manufacturers, from retail dealers, or, with the exception I have mentioned, from professional men, in opposition to the recommendations which they have made; and amongst the members of the Committee the one opponent of their recommendations was Mr. Stevenson, who added a report of his own, which is printed with the evidence, but which did not find a seconder. Reference was made to the fact that, in the Parliamentary Report of a Committee which sat thirty-three years ago on this subject, two very distinguished men of science—*i.e.* the late Astronomer Royal, Sir George Airy, and Sir John Herschel—expressed strong opinions in opposition to the adoption of the metrical system. One witness, Lord Kelvin, on being asked by the Chairman how far in his opinion that evidence applies at the present time, answered: "I believe these two great men would see things very differently now; their minds had not been opened to the great advantages of the metrical system. Since they gave that evidence every country in Europe has accepted the metrical system except ourselves, and the general understanding of these subjects has certainly advanced very much"; and he went on to say that he did not think that at the present moment a Committee on the subject need consider the objections thus raised thirty years ago as being of importance; on the contrary, he would like to see the metrical system made compulsory after the lapse of a certain period, and would not be satisfied without a thorough adoption of this as the only legal system in the country. Moreover, he did not think decimalisation of the coinage was at all a necessary accompaniment for the adoption of the metrical system of weights and measures.

Further evidence went to show that in the United States the metrical system was actually legal, was in use within the State of Utah, and has been adopted as a compulsory system for all pharmaceutical and medical purposes; that this latter also is the case in Russia; and quite recently the announcement has been made that in the new edition of the "British Pharmacopœia," about to be issued, the metrical weights and measures will be adopted. It appeared to be a general opinion amongst witnesses consulted by the Committee that it only requires that England should take the initiative, in order that both Russia and the United States—the only civilised countries now not using the system—should at once adopt it, and thus all nations would have one and the same system, and that this would be an incalculable benefit to mankind.

Mr. Balfour is reported by the *Times* to have replied as follows: "I have listened with very great interest to the powerful speeches that have been made upon the important subject with regard to which we are met here to-day. If I may express my own opinion upon the merits of the case, there can be no doubt I think whatever that the judgment of the whole civilised world, not excluding the countries which still adhere to the antiquated systems under which we suffer, has long decided that the metric system is the only rational system. Scientific men in this country have long been driven to use it in their writings, to use it in their calculations, and, if I may so express it, to think in it, to think out the problems in which they deal in the system which we owe to the ingenuity of the French. What men of science have long been obliged to do—not merely because the international character of science makes it desirable, but also because the calculations are so much more rapid, so much more convenient—what men of science for those reasons are obliged to do, I believe that commercial firms in all parts of the country are beginning to think they must do also. On that point I do not think that argument is possible. The solitary argument which appears to have been alleged on the other side is that the existing English system is a good gymnastic for the mind. I dare say it would be a very good gymnastic for the body if, instead of having macadamised roads, we were obliged to make our way over pathless heaths and plunge through ditches and over hedges; but though it would be an excellent gymnastic for the body it would not be a convenient method of getting from place to place, and I do not think any one is likely to recommend that we should return to the primitive kinds of locomotion once used by our forefathers. There appears, therefore, to be an absolute agreement on the merits of the case. There is no such agreement with regard to the practicability or the ease of carrying out any great change. We in this country are rather in the condition of an industrial concern which was using antiquated plant, but which felt that it could not renew that plant according to modern requirements without an immense expenditure of capital which for some years would destroy all the profits, or a large part of the profits, of the undertaking. In precisely the same way, while everybody admits that the change when once effected would be a change of almost universal beneficence, I think we ought not to conceal from ourselves that there would be loss and inconvenience during the period of transition. I think we have only got to consider our own personal experience to see that that is so. Like the rest of the world, I have had to read books in which the metric system was the one in use. As I have been brought up on the English system, there has always been a certain difficulty in representing to the imagination without effort and immediately by an automatic process exactly what was intended. To translate miles into kilometres is not a very difficult process, but it is not automatic even to the person who knows the exact length of the kilometre and mile. And what is difficult to us who have been to a certain extent habituated to both systems, would certainly be difficult to the great mass of retail traders and the great body of the poor. They have been accustomed to think in one kind of measure, and to require them by law suddenly to think in another kind is to compel them to go through an effort which I think every one will admit would be an arduous effort in some cases, and an effort which would not be unaccompanied by mistakes and difficulties on the part of those who are unaccustomed to it. It is a matter, it will be observed, largely of familiarity and imagination. We all know what we mean by a yard. To translate that into a metre requires a little effort. We all know what we mean by a mile, to represent it in the imagination, but to translate it into a kilometre requires an effort, and I do not think we should underrate the obstacles in carrying out the beneficent change. I was struck by what fell from Sir Henry Roscoe and some other members of the deputation with regard to the extraordinary vitality in England of antiquated and illegal weights and measures in different parts of the country. Although our existing measures are the only legal ones, it appears that other measures are in habitual use by large portions of the population. If old measures are so difficult to kill, as they clearly are, we must not forget that we have a very heavy task before us to bring about the great change of the existing system to the decimal system. I have been informed that in France, where the metric system has now long been in use, where it is universally believed in as the only rational system, I believe that even in France, in some parts, the population prefer some of the old measures which their fathers were accustomed to rather than the rational system which has now for more than two generations been the only legal one in force. Therefore we ought not to approach the solution of this problem in too sanguine a spirit. I observe that there are three recommendations which the Chambers of Commerce have formulated and embodied in the memorial presented to me to-day. The first is that the metrical system of weights and measures should at once be legalised for all purposes. The second is that it should be the only legal system allowed in this country after two years. The third is that every effort should be made to teach it in the elementary schools. With the first and third of these I find myself in entire agreement. I am told that there are legal obstacles to the use in all trades, and I am quite unable to see why that obstacle should be continued. I think it is our business to do everything we can to smooth the transition from the old to the new system, and certainly the first step towards smoothing that transition would be to make legal that which we think desirable and which we may ultimately think necessary. I was struck by an observation from Mr. Arnold-Forster in regard to the standing orders of the House of Commons, and to the exclusion of the metric system from our national manufactures—that is, manufactures undertaken by the Government. I think both of those are topics well worthy of consideration, and I shall consult with my friend Mr. Ritchie and the other departments of the Government concerned to see whether from either of those points of view anything can be done to meet the general wishes of the commercial classes as represented by the Chambers of Commerce. With regard to the teaching of the metric system in elementary schools, I believe something has been done already in that direction by the Education Department, but on that topic also I shall consult

Sir John Gorst and see whether we cannot do something to spur on the teaching of the metric system in the schools, and thereby familiarising the imagination of the rising generation to a system which perhaps ultimately will be the only one they will be permitted to use. With regard, however, to the second proposition in the order of statement by the Chambers of Commerce, you will have gathered from what I have said that I should see very great difficulties in compelling every class in the community suddenly to alter its familiar and habitual practice in regard to the weights and measures in which it deals. If I may venture to say so, I hardly think that the Chambers of Commerce, or even the trade union congresses, are adequate representatives of the kind of feeling which would probably animate the great mass of small retail dealers and those who buy their goods from such dealers, who would suddenly find all their familiar landmarks swept away and unfamiliar things put in their places. You represent the great commercial interests of the country, and possibly you might find a degree of opposition to your proposals which you little anticipated if you were to endeavour to drive into every cranny of our social system changes which no doubt would be very beneficial as applied to the great industries and manufactures. That leads me to ask—if the advantages of the metric system as compared with the existing system be so great as you tell me they are, as I fully believe they are—whether they could not now be adopted, for instance, in shipbuilding yards on the Clyde, in the great machine-making industries of Manchester, and in such commercial centres as Belfast. I think one gentleman did mention a firm which had employed it, and which had no difficulty in employing it. The engineers do it now, and they have not found much difficulty in doing it, and they have derived much benefit from it. Surely it is within the province of private enterprise to extend that system to every one of the great industries which bring us into relation with foreign countries. The foreign meat trade is already largely carried on on a decimal system, but not the metric. What I want to insist upon is that, while it is of great importance to render such a change easy, it is within the province of private enterprise to carry it out gradually in those great industries. I cannot but believe that if you represent, as I am sure you do, the feeling of the great industries in this matter, we shall find, without any compulsion on the part of the Government at all, the metric system making its way through all the leading industries. It must be legalised certainly, but, when legalised, it will make its way. It is evident that, in so far as that process is carried on, you would enormously facilitate that ultimate compulsory change to which we all look forward, but which, I think, could not, with safety or advantage, be undertaken by the Government till public opinion is more prepared for it than at present. The public opinion with which we have got to deal, and which we are bound to consider, is not the public opinion of the great manufacturers alone, but the public opinion of every man and woman you meet in the street. While I look forward to the time, and no distant time, when they will adopt the change without difficulty and without repugnance, I should like to see private enterprise do more than it has done up to the present to show that the change can be adopted without inconvenience, and that it carries with it all the benefits which I, in common with you, firmly believe to be attached to the metric system, and which it is impossible to associate with the arbitrary, perverse, and utterly irrational system under which we have all had the misfortune to grow up."

NOTES.

A LARGE and influential deputation is to wait on the Duke of Devonshire at noon to-day to urge on the Government the importance of introducing, at an early date, a Bill appointing a Statutory Commission to give effect to the recommendations of the late Royal Commission on the London University question.

THE first meeting of the General Committee of the Huxley Memorial was held, under the presidency of the Duke of Devonshire, yesterday, as we went to press. The chief object of the meeting was to decide the form which the memorial should take. The long list of the General Committee, consisting of the names of men of light and leading in all parts of the world, is a striking testimony to Huxley's greatness.

THE Egyptian Government have determined to commence a geological survey of the "land of Egypt." The work will be begun next year, and will take about three years for its completion, the estimated cost being £25,000. To carry out the proposed plans, a wise selection of a geologist has been made in the person of Captain H. G. Lyons, R.E., who is at present engaged (under the Public Works Department of the Egyptian Government) in superintending the excavation of the ruined temples of Philæ. Captain Lyons has already written an excellent article on the "Stratigraphy and Physiography of the Libyan Desert of Egypt" in the Geological Society's *Journal* for 1894, and has also made extensive explorations on the Upper Nile. Had the Egyptian Government taken this step some years ago, they might have saved some considerable sums of money which they have squandered in searches for petroleum and various minerals, undertaken at the instigation of inexperienced and interested advisers.

A SHARP earthquake shock occurred at Athens at 7.30 on Wednesday morning, and was also felt at Chalcis, Livadia, Thebes, and Corinth.

DR. J. D. GILCHRIST has been appointed Marine Biologist to the Government of the Cape of Good Hope. He will be charged with the investigation of the marine resources of the country, especially in their practical relations to the fisheries.

A COMMITTEE has been formed to make arrangements for presenting to Prof. Adolf Bastian, Professor of Ethnology in Berlin, a volume of original essays on various branches of ethnology, anthropology, and kindred sciences, when he attains his seventieth birthday in June next.

WE learn from the *Lancet*, that the Health Committee of the Glasgow Town Council has decided to establish and equip a complete bacteriological department in the sanitary buildings now in course of erection. The laboratory is to be in charge of an expert in bacteriology.

THE *British Medical Journal* states that Prof. Loeffler, of Greifswald, the discoverer of the diphtheria bacillus, has received from the French Government the Officer's Cross of the Legion of Honour.

DR. CARTWRIGHT WOOD has been granted £100 out of the Goldsmiths' Company's grant allocated by the Committee of the Conjoint Laboratories of the Royal Colleges of Physicians and Surgeons, for investigations as to improved means of treating horses with a view to obtaining diphtheria antitoxic serum in a shorter time than is possible by the methods hitherto in use.

OUR contemporary *Invention* has lately been brought out in a popular penny series. We hope and believe that in this form it will play a useful part by showing to a wide circle of readers some of the work that has been, and is being, done in the world of science, and by indicating how intimately scientific research is connected with industrial progress.

WE notice with regret the death of Mr. J. Traill Taylor, editor of the *British Journal of Photography*. He was in his sixty-ninth year, and was widely known and respected in photographic circles. We have also to record the death of Prof. George Lawson, Professor of Chemistry and Mineralogy in the University of Halifax, Nova Scotia, and formerly President of the Royal Society of Canada.

THE death is announced of Surgeon-Major George Edward Dobson, F.R.S., at the age of forty-seven. He was awarded the gold medal of the Dublin Pathological Society in 1867 for his essay on the diagnosis and pathology of the injuries and diseases of the shoulder-joint. He also wrote "Medical Hints to Travellers," published by the Royal Geographical Society;

"Monograph of the Asiatic Chiroptera," 1876; "Catalogue of the Chiroptera in the British Museum," 1878, a complete natural history of the order; and "Monograph of the Insectivora, Systematic and Anatomical," in which the zoology and anatomical structure of the species were concurrently investigated; and he was the author of numerous other articles, published in the *Proceedings* of various scientific societies and in scientific journals. He was elected into the Royal Society in 1883, and was a corresponding member of the Academy of Natural Sciences of Philadelphia and of the Biological Society of Washington.

A GREAT Frenchman has just passed away in the person of M. Barthélemy Saint-Hilaire. He was born so far back as August 19, 1805, and the fiftieth anniversary of his election into the Academy of Moral and Political Sciences was celebrated in 1889 at the Institute of France. Like many other men in France, he was both philosopher and statesman. He translated the complete works of Aristotle, and was the author of numerous original works. He spent some time in a journey to Egypt with M. Ferdinand de Lesseps, to explore the Isthmus of Suez; and he shared to the full the firm belief of the creator of the Suez Canal in the feasibility of the undertaking. After his return from Egypt he published his "Letters on Egypt," 1856, and "Egypt and the Great Suez Canal," 1857. In 1860 M. Saint-Hilaire published his work on "Buddha and his Religion"; in 1865 appeared his "Mahomet and the Koran," preceded by an introduction on the Mutual Duties of Philosophy and Religion, and in 1866 his "Philosophy of the Two Ampères." He was Secretary-General of the Presidency of the French Republic, after the war of 1871. Upon the fall of M. Thiers, he resumed his great translation of Aristotle. In 1880, at the age of seventy-five, he became Minister for Foreign Affairs in the Jules Ferry Cabinet, from which he retired on the accession to power of Gambetta in 1881.

A COMPLETE change in the type of weather took place over the British Islands during the latter part of last week. The *Daily Weather Report* of the 23rd inst. showed that an area of high barometric pressure was spreading over our western coasts from the Atlantic, while an area of low barometric pressure, which had formed over the North Sea, was crossing the Netherlands. During the following days this disturbance passed to the south of Italy, and, in connection with very high barometer readings in Scandinavia, its passage caused strong north-easterly and easterly gales in the south and east of England, and very high seas in the English Channel, while on the continent it was accompanied by much snow and sleet. Although the force of the wind was not so strong inland, the pressure recorded at Greenwich Observatory on Sunday was 16 lb. on the square foot, which by the revised factor for the conversion of wind pressure to velocity is equivalent to a rate of about 76 miles in the hour.

THE terms of the competition for the Thousand Guinea Prize offered by the *Engineer* for mechanical road carriages are published in the current number of our contemporary. The limit of weight has been fixed at two tons, and the speed at ten miles an hour; while in the case of oil being used as the motive power, the flashing point is fixed at 73° F. The competition, it is thought, cannot take place before October 1896, when the various vehicles—two classes of two tons each, and two of one ton each—will be required to run 200 miles, and Sir F. Bramwell, Mr. J. A. F. Aspinall, and Dr. John Hopkinson will act as judges.

THE convention between Italy and Switzerland for the construction of the Simplon Tunnel was signed at Berne on Monday. The programme of the works to be followed is that already approved by the Jura-Simplon Company, the Swiss Federal Council, and the Italian Government. When the tunnel is completed, the nearest seaport for French Switzerland, Haute Savoie, and the Valais will no longer be Marseilles, but Genoa, and the shortest route from Milan, Piacenza, Venice, Genoa, and Trieste to Paris will be through the tunnel.

WE learn through the *Times* that the United States Nicaragua Canal Commission, appointed by President Cleveland last spring, has reported that it is neither advisable nor practicable to attempt the construction of a canal upon the data at present available. New surveys are needed before any final judgment can be formed, but the provisional estimate of the cost by this Commission is about £27,000,000, nearly double the Maritime Canal Company's conditional estimate. That Company's report is very strongly criticised in detail and in general, to the effect that it is not based on a thorough knowledge of the physics of the site. Their proposed dam in Ochoa is regarded as unsafe, dangerous, and subject to floods, the proposed entrance to Greytown Harbour is deemed wrongly placed, and the canal itself is considered inadequate in width and depth. The numerous technical criticisms of this report all point in the same direction—namely, that no such canal as that contemplated by the Maritime Company can be built in the way which they design, or for the money which they would expend upon it.

THE opening meeting of the Conference convened by the Board of Trade on the subject of the revised regulations proposed to be made under the Electric Lighting Acts, 1882 and 1888, was noted in our last issue (p. 60). We extract from the *Times*' report of the second day's proceedings the more important decisions arrived at. The Chairman, Sir Courtenay Boyle, stated that he had carefully considered the very important representation made the previous day on the subject of the definition of low pressure, and he thought it would be for the convenience of those interested if a decision were reserved for a short time, so that the Board of Trade might appoint a small committee, not exceeding three, of expert advisers, carefully to consider the scientific aspect of the question, and to make a suggestion to the Department. This was approved by the meeting. The discussion of Clause 35 of the revised regulations relating to street boxes, pointed to the need for a definition of street boxes, and led the Chairman to suggest that the clause should apply only to street boxes containing transformers. It was agreed that the clause should read thus: "In the construction of street boxes used as transformer chambers reasonable means shall be adopted to prevent as far as possible any influx or accumulation of gas or water either from the adjacent soil or by means of pipes; and ample provision shall be made by ventilation or otherwise for the immediate escape of any gas which may by accident have obtained access to the box, and for the prevention of danger from sparking." The Chairman promised to consider whether the Board of Trade could make a regulation for the ventilation of street boxes of a certain dimension. Opposition was offered to Clause 37, which provided that "the casing of any high-pressure electric lines shall be continued within street boxes," and the Chairman said the clause would be struck out on the understanding that it might be necessary to continue the old regulation, so as to prevent danger arising by high-pressure lines passing through transformer chambers not being properly cased. Objections having been raised to Clause 38, relating to converting stations, the Chairman said he thought the old regulation would better meet the case. That regulation was as follows: "Converting stations, or points in a system of distribution to which a high-pressure supply is given from generating stations, and from which a low-pressure supply is given to one or more consumers, and which are not on the consumer's premises, shall be established in suitable places, which are in the sole

occupation and charge of the undertakers." After discussion the Chairman accepted Clause 41 in the following form: "A suitable safety fuse or other automatic disconnector shall be inserted in each service line as close as possible to the point of entry in any consumer's premises, and contained within a suitable locked or sealed receptacle of fireproof construction, except in cases where the service line is protected by fuses in a street box." A few other regulations having been discussed, the proceedings of the Conference terminated.

A RARE British bird invites the attention of ornithologists in the Fish House of the Zoological Society's gardens. This is a Spotted Redshank (*Totanus fuscus*) in winter plumage, recently obtained from the fens of Lincolnshire, being the first individual of this species that has been received by the Society.

IT is well known that liquid ammonia relieves the effects of the stings of bees. A correspondent informs us that a much more effectual antidote is the mixture known as ammoniated tincture of quinine. On several occasions, when stung by bees, he found that the quinine mixture would give much quicker and greater relief than ammonia alone.

WITH reference to their letter on the thermal conductivity of rocks, published in our issue of the 7th inst., Messrs. Peirce and Willson desire to say that the phrase "recent discussion in NATURE" refers to communications printed in these columns previous to June 20. When they wrote their letter, they had not seen the account of the experiments of Lord Kelvin and Mr. Murray, published in NATURE of that date (vol. lii. p. 182).

A CORRESPONDENT writes:—"On November 19 of this year, some yardsmen were turning over some English oak planks, prior to stacking them, at Messrs. Harry Hems and Sons at Exeter, when one of the men put his hand in a knot-hole that occurred in a 6-inch thick plank. He instantly withdrew it with a cry, and some wasps flew out. On examination, the hole was found to contain a large nest with sixty or seventy wasps in it. The plank and its living contents had come, with a number of others, from Lincolnshire by rail a few days before. Probably this long ride for a wasp's nest beats the record!"

SOME of the officers of the new Ashantee Expedition, who have leisure for sporting pursuits on their march up to Coomassie, will do well to secure for the National Collection additional specimens of the Royal Antelope (*Neotragus pygmæus*), which are much wanted. This little animal, discovered by Bosman in 1704, and named the "King of Harts," and subsequently figured in Seba's "Thesaurus," although so long known to science, is still a scarce object in our museums. In fact, as Messrs. Sclater and Thomas tell us in their "Book of Antelopes," all the small members of this group, both of West and East Africa, are still very imperfectly known, and additional specimens and information on them are much required.

IN the course of his researches on the smaller mammals of South America, Mr. Oldfield Thomas, of the British Museum, has made a brilliant discovery. A small rodent, not quite so big as a rat, which he has lately named *Cænolestes obscurus*, turns out to be closely related to, and a surviving representative of, some of the Fossil Marsupials recently described by Ameghino from the Santa Cruz beds of Patagonia. It therefore belongs to a new family, quite distinct from all hitherto known existing forms of the Marsupial order. Mr. Thomas's paper on this subject will be read at one of the Zoological Society's next meetings.

"CARBONIC snow," or carbonic acid crystals, form the subject of an interesting paper by MM. P. Villard and R. Jarry in the November number of the *Journal de Physique*. Using a toluene thermometer, they found that in the open air it kept at a constant temperature of $-79°$ C. This is in fact its boiling point, but whatever liquid is formed is at once frozen by the cold caused by evaporation. Hence the gas is only slowly given off. To prevent radiation, it should be kept in a glass silvered on the outside. The solid "snow" is, by the way, heavier than the liquid carbonic acid, in spite of its apparent lightness. No hoar-frost forms on the surface, owing to the constant evolution of the gas. Another vexed question is that of the temperature of the solution of the "snow" in ether. Accurate measurements showed that, contrary to the popular idea, this solution is not a freezing mixture, its temperature being $-79°$ C., the same as that of the solid. Methyl chloride does, on the other hand, form a freezing mixture of the temperature $-85°$ C. In a flat dish this becomes $-88°$ C., and when a current of air is blown through, $-90°$ C. In a vacuum of 5 m.m. of mercury, the temperature falls as low as $-125°$ C. Since this is below the critical temperature of oxygen, there seems no reason why oxygen should not be liquefied by the aid of carbonic acid alone.

THE common crow has a bad reputation among agriculturists, but a report, by Prof. W. B. Barrows and Mr. E. A. Schwarz, on his habits in the United States (*Bulletin* No. vi., U.S. Department of Agriculture), shows that even his character is not so black as it has been painted. The most important charges brought against the crow are that it pulls sprouting corn, injures corn in the milk, destroys cultivated fruit, and feeds on the eggs and young of poultry and wild birds. All these charges are sustained by the results contained in the present report of the examination of the contents of nearly a thousand Corvine stomachs. Crows do certainly feed upon the substances named, but the extent of the injury they do is quite another matter. In order to ascertain whether the sum of the harm done outweighs the sum of the good, or the contrary, the different kinds of food found in the stomachs have been reduced to quantitative percentages, and then compared. The results show that only 3 per cent. of the total food of the crow consists of sprouting corn and corn in the milk; the remaining 97 per cent. is chiefly waste grain picked up here and there, mainly in winter, and of no economic value. In the case of cultivated fruits, the loss due to crows appears to be trivial. The same is true of the eggs and young of poultry and wild birds, the total for the year amounting, in the cases examined, to only 1 per cent. of the food. As an offset to his bad habits, the American crow is credited with the good done in destroying noxious insects and other injurious animals. Insects form 26 per cent. of his entire food, and the great majority of these are grasshoppers, beetles, weevils, cutworms (larvæ of Noctuidæ), and other injurious kinds. To the same side of the scale must also be added the destruction of mice, rabbits, and other injurious rodents by the crow. Wherefore Mr. Hart Merriam concludes, in his introductory note to Messrs. Barrows' and Schwarz's valuable report, that, in summing up the benefits and losses resulting from the food habits of this bird, the good exceeds the bad, and that the crow is a friend rather than an enemy of the farmer.

THE efficiency of windmills and agricultural apparatus forms the subject of a note, by Prof. Cleveland Abbe, in the *Monthly Weather Review*. There are many important and expensive agricultural machines, such as reapers, mowers, windmills, and pumps, to say nothing of portable steam-engines, that are needed on large farms, or the centrifugal separators used in dairies, that fail to give satisfaction because of some inherent mechanical defect. The most efficient machine is that which produces the best result with the least possible waste of power. Prof. Abbe suggests that there be some recognised authority to come between the manufacturer and the farmer; some one who shall "standardise" any piece of apparatus when desired, and

certify as to the amount of power that is lost, or as to the efficiency of the machine when working under its best possible condition. Mechanical engineers are accustomed to determine very accurately the relation between the work done and the force expended; but no arrangement has yet been organised in America, though in England the Royal Agricultural Society does something by means of which the farmer may obtain, for a small fee, accurate information as to the efficiency of the windmills, pumps, and other apparatus used by him. Such tests are sometimes applied, but oftentimes imperfectly, to machines that are offered in competition for prizes at shows; but the results apply only to those specific samples, and not to others that are ordinarily found in the market. There are standards for the sale of illuminating gas, electricity, and other sources of energy. The time may come, concludes Prof. Abbe, when Governments will standardise and regulate the sale of the machines for the conversion of force or the doing of work.

THE current number of the *Journal de Physique* contains a description of an instrument for measuring the specific inductive capacity of liquids or solids, designed by M. Pellat. The instrument consists essentially of two Kelvin attracted disc electrometers, in which the two movable discs are rigidly connected together. The two attracting discs are in metallic connection, and one of them can be moved by means of a micrometer screw. The attracted discs are attached to the arm of a delicate balance, the position of the beam being observed by a microscope. An air damper attached to the beam serves to check the oscillations, which otherwise would render the measurements extremely tedious. Weights are used to roughly counterpoise the weight of the attracted discs when the whole instrument is at one potential. The final adjustment is made by means of a fine spiral spring, attached to the arm of the balance, and which can be stretched more or less by means of a micrometer screw. This spring has the advantage of increasing the range of potential difference over which the position of the balance is stable. The substance to be examined—if a solid in the form of a slab, or if a liquid contained in a glass dish—is placed between the fixed attracting disc and its movable disc, being supported on three small glass blocks which rest on the guard-ring. Readings of the position of the movable attracting disc are taken with and without the substance in place, and from the difference of the readings the specific inductive capacity is calculated. The sensitiveness of the instrument is such that the author has been able to measure, roughly it is true, the specific inductive capacity of mica, using a plate of this substance only 0·013 c.m. in thickness. In the case of liquids, measurements have been made in which the one set of plates, attracting plate, attracted plate and guard-ring, were entirely immersed in the liquid. The effect of capillarity on the stem joining the two attracted discs was to very much increase the range of potential difference giving stability of the balance. It was found that at the moment of applying the difference of potential an initial and very sharp movement always takes place when the balance is not perfect; so that the measurements could be made with an accuracy as great as in the case of solid dielectrics.

WE have received from M. A. Lancaster, of the Royal Observatory, Brussels, a pamphlet containing his communications to the Congress of the Science of the Atmosphere, held at Antwerp last year: (1) On synoptic weather charts, advocating the establishment of an international meteorological institute, acting on the part of all countries, and the pubiication of weather charts for extensive areas. The question of an international institute for meteorology has frequently been discussed, and at the recent meeting of the International Meteorological Committee at Upsala it was decided that the idea was not practicable. But the author points out that in the cases of geodesy and metrology such institutions have long been established. (2) On the nature of the wind. The principal object of this paper is to draw attention to the similarity of the views of the late M. Houzeau (formerly director of the Brussels Observatory) to those of Prof. S. P. Langley, expressed in his treatise on the internal work of the wind (NATURE, vol. xlix. p. 273), in which he shows that the wind consists of a succession of pulsations of very short duration, of variable amplitude and direction, relatively to the mean movement of the wind. (3) On the strength of the wind in Belgium. This paper contains tables of the principal results of observations at Brussels from 1850 to 1889, showing *inter alia* the mean monthly velocity, the bi-hourly variation, the maximum velocity and its direction in each month. These tables afford valuable information for architects and engineers, and for any one requiring details as to the effect of the motion of the atmosphere.

RESPONSIBLE measle-microbes, although suspected, have long eluded the diligent search of the investigator. Dr. Joseph Czajkowski, however, appears to have opened up the subject afresh by bacteriological researches which he has been carrying on for nearly four years on cases collected from four different epidemics of measles. Although the total number of cases bacteriologically examined was not great, amounting to only fifty-six in all, yet in every instance the same microbe was identified from the blood of measle patients, and is described as being a somewhat slender bacillus with blunted ends, producing occasionally threads in cultures some months old. No difficulty is experienced in staining it with the usual aniline colours, and in drop-cultures it is seen to be very motile. Gelatine and agar are not suitable for its growth; on the other hand, glycerin-agar and broth form convenient culture materials. As regards the pathogenic properies of Dr. Czajkowski's bacillus, the information is only at present limited to its action on rabbits and mice. The former experienced no inconvenience whatever after being inoculated with it, but the mice died in from three to four days, exhibiting symptoms of septicæmia, and the same bacillus was subsequently obtained in pure cultures from the blood, spleen, and liver of the infected animals. Perhaps the strongest evidence in favour of the author's researches is to be found in the fact that two other investigators, P. Canon and W. Pielicke, working at the subject quite independently of Dr. Czajkowski, discovered the same bacillus. Further inquiries must, however, be made before we can define with certainty the precise relationship to measles possessed by this new microbial claimant.

THE last number of the *Mittheilungen von Forschungsreisenden und Gelehrten aus den Deutschen Schutzgebieten*, Bd. viii. Ht. 3, continues the scientific description of the German colonies. The first contribution deals with the Hinterland of the Cameroons, from materials collected during Dr. Passarge's expedition during 1893 and 1894. Schnauder has worked out a series of twenty longitudes. Passarge gives the data on which the altitude determinations rest, and some of the results. Dr. Limpricht has prepared three maps of the district on the scale of 1 : 350,000, and connected Passarge's routes with those of previous travellers in this region, viz. Barth, Flegels, Maistre, Zintgraff, and Baikie. The second contribution in the number is Stühlmann's description of the Uluguru Mountains, a district in German East Africa between Usambara and Usagara, and about one hundred miles inland. Geologically it consists mainly of gneiss, with some clay-slates, oolitic limestones and red sandstones, on the plains at the eastern foot of the mountains. Mica and graphite were the only minerals found, which Dr. Stühlmann thinks may be of economic value. The gneiss forms a plateau, to the east of which are the steppes of the "Vorland." The former is regarded as healthy and free from malaria. The author of this report has previously expressed the belief that

the climate of eastern equatorial Africa was more humid than at present: he now attributes the change to artificial deforestation of the country. The most interesting paper in the number is one by St. Paul Hilaire, which gives an account of the laws of inheritance of the different tribes on the coast near Tanga. In the actual coast towns the people are either Mohammedan, or under Mohammedan influence, and the author has little new to record, except a list of native writings. The Bantu people of the district considered belong to four tribes, of which the report deals only with the Wa digo, one of the most intelligent people on the East African coast. St. Paul-Hilaire first states the laws on the inheritance of property, which passes to the relatives of the mother. Thus a man's wives and children are inherited by the nearest male maternal relative. The rest of the report summarises the rules in regard to marriage. The last article in the volume continues the publication of Dr. Steinbach's important meteorological observations on the Marshall Islands.

FOR several years the American Public Health Association has had a special committee on pollution of water supplies. At the meeting of the Association in Montreal, this committee recommended that a co-operative investigation be instituted with regard to the bacteriology of water supplies, and, as an outcome of this proposal, a convention was held in New York, in June last, to consider methods and elaborate a standard scheme of work which would secure some sort of uniformity in the differentiation of species of bacteria. The verbatim report of the proceedings of this convention (which was attended by most of the prominent American bacteriologists), together with the papers presented, make up the October *Journal* of the Association. The subjects considered relate almost exclusively to certain technical matters, which required elucidation before a satisfactory scheme of work could be drawn up; among these questions being: colour nomenclature for bacteriologists; how variability is to be regarded; the methods to be followed in determining the relation of bacteria to temperature; methods for the separation of bacteria into groups, and for the identification of species; the nature of the flagella, and their value in the systematic classification of bacteria; the grouping of water bacteria, and the influence of variations in the composition of nutrient gelatine upon their development. No decision was reached on any of the questions discussed; but the whole series was referred to a committee, with the understanding that the convention would accept its decision, and that its members would modify their laboratory methods in accordance therewith. The decisions of this committee have not, however, yet been published.

THE literature of marine biology has just been increased by the publication of the fourth volume of "Reports upon the Fauna of Liverpool Bay and the neighbouring Seas," written by the members of the Liverpool Marine Biology Committee and other naturalists, and edited by Prof. W. A. Herdman, F.R.S. The volume commences the record of the investigations carried on at the committee's biological station at Port Erin, Isle of Man. At this station, which was opened in 1892, several important investigations have already been carried out, and there is every reason to believe that the work will develop in the future, as the facilities for observations are increased. We notice among the papers included in the volume, one on the vascular systems of the Starfishes, by Mr. H. C. Chadwick, and another on the Cerata of Nudibranchs, by Mr. J. A. Clubb. There are also reports on Turbellaria, by Mr. F. W. Gamble; on Copepoda, by Mr. Isaac C. Thompson; on Nemertines, by Mr. J. H. Vanstone and W. I. Beaumont; on Medusæ, by Mr. E. T. Browne; and on Amphipoda, by Mr. A. O. Walker. These, with a valuable paper, by Dr. R. Hanitsch, on the nomenclature and classification of British sponges, and three reports, by Prof. Herdman, upon the work of the Liverpool Marine Biology Committee and their biological station, make up a very creditable volume. The Liverpool naturalists deserve to be congratulated for accomplishing so much work in a modest establishment, and without any funds except those raised by private subscriptions.

TWO memoirs on Entomophytes have recently been published. The one is by Mr. R. H. Pettit on "Studies in Artificial Cultures of Entomogenous Fungi," and emanates from the Cornell University Agricultural Experiment Station, U.S.A. The other is by Mr. A. S. Olliff on "Australian Entomophytes, or Entomogenous Fungi, and some account of their Insect-Hosts," and is issued by the Department of Agriculture, Sydney, N.S.W. Both are well illustrated, and deal largely with Cordyceps and Isaria. The loose, white, cottony growth which sometimes envelopes dead insects is a familiar sight, and Mr. Pettit, in discussing the possible use of entomogenous fungi for insecticidal purposes, refers to the suggestion that has been made to employ *Sporotrichum globuliferum* against the chinch-bug. Mr. Olliff is prepared to make the assertion that all the larger fungi of the genus Cordyceps live upon, and at the expense of, subterranean larvæ and pupæ, in proof of which he points to the fact that all the bulky species of which the hosts are definitely known have been found upon root-feeding insects. Of Hyphomyceteæ there are various minute entomogenous forms recognised as Australian. Some of these are variously found on aphides infesting pumpkin leaves, on dead ants, and on red scale of the orange. *Botrytis tenella*, Sacc. (*Isaria densa*), on larvæ and pupæ of Diptera, wasps, and cockchafers, has been introduced into Australia from Europe for the purpose of killing Lamellicorn larvæ, but the attempts have not succeeded. Mr. Olliff adds that in view of the large numbers of *Cordyceps Gunnii*, and *C. Selkirki* that are found in a limited area, and of the extensive injuries to useful timber and shade trees which often result from the attacks of the subterranean larvæ of Pielus and Trictena, the hosts of these parasitic fungi, it is evident that the native species of Cordyceps have a considerable economic value. He hopes that the Department of Agriculture at Sydney will shortly be able to make investigations to test the possibility of utilising these fungi artificially for the destruction of injurious root-feeding insects.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. V. Roger; a Smooth-headed Capuchin (*Cebus monachus*) from South-east Brazil, presented by Major F. A. White; a Kittiwake (*Rissa tridactyla*), British, presented by Mr. Walter Butters, jun.; three Poë Honey Eaters (*Prosthemadera novæ-Zealandiæ*) from New Zealand, presented by Mr. Morton Campbell; a Bearded Lizard (*Amphibolurus barbatus*), a Diamond Snake (*Morelia spilotes*) from Australia, presented by Mr. Frederick G. Aflalo; a Four-lined Snake (*Coluber quadrilineatus*), European, presented by Captain Allen Keys; a Poë Honey Eater (*Prosthemadera novæ-Zealandiæ*) from New Zealand, deposited.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—A bright comet was discovered by Mr. Brooks, at Geneva, on November 21, in R.A. 9h 52m. and Decl. 17° 4′ S. An observation of the comet at Copenhagen shows that it is moving northwards at the rate of nearly three degrees per day. On November 24, at 17h. 37m. 9s., it was in R.A. 9h. 42m. 33s. and Decl. 10° 40′ 32″ S. The comet is not far from α Hydræ, and rises about 12.30 a.m.

COMET PERRINE.—The comet discovered by Mr. Perrine at the Lick Observatory, on November 16, was observed by Dr. Lamp at Kiel, on November 18, its position at 17h. 34·2m. Kiel mean time being R.A. 13h. 48m. 8s., Decl. 0° 50′ 24″ N. *Edinburgh Circular* No. 47 reports that the comet was also

observed by Dr. Halm, at Blackford Hill, as follows:—November 18, 18h. 26m. 14s. G.M.T.; R.A. 13h. 48m. 15s., Decl. 0° 48′ 18″·8 N. The movement of the comet is in a direction south-east by east, and it now rises about 4 a.m. Dr. Lamp states that the comet is moderately bright, but not visible to the naked eye; it is round, with a central condensation, and a straight tail (*Ast. Nach.* 3318).

VARIABLE STAR CLUSTERS.—Harvard College Observatory *Circular*, No. 2, announces that an extraordinary number of variable stars has been discovered in certain globular clusters which have been photographed by Prof. Bailey at Arequipa with the 13-inch Boyden telescope. At least eighty-seven of the stars in the cluster M3 (N.G.C. 5272), in Canes Venatici, have been found to be variable, and in some cases the change of light amounts to two magnitudes or more. In the cluster M5 (N.G.C. 5904), forty-six variables were found, out of 750 stars examined, so that they form about six per cent. of the whole; of the sixteen stars, contained in a circle 110″ in diameter, six are variable. Smaller numbers of variables have been found in other clusters, but in other cases not a single variable has been detected out of the hundreds of stars which have been photographed: the conditions of the search, however, not taking account of long period changes. In general, no variables have been found within about one minute from the centres of the clusters, on account of the closeness of the stars, and none are more than ten minutes distant from the centres. Some of the newly-discovered variables have short periods, in some cases of only a few hours. Thus, five photographs of N.G.C. 5904, taken at intervals of an hour on July 1, 1895, give for the magnitude of a star about three minutes of arc preceding the centre of the cluster, 14·3, 13·5, 13·8, 13·9, and 14·3: four plates, taken at similar intervals on August 9, gave the magnitudes 14·2, 14·6, 14·8, and 15·0.

ON A METHOD OF PHOTOGRAPHY IN NATURAL COLOURS.[1]

IN 1861 Clerk Maxwell described a method of colour photography, based upon his experiments on the theory of colour vision, and made the following experiment. Three photographs of a coloured object were taken through three several coloured solutions giving images which separately represented the object as it would be seen by each of the three sets of colour nerves postulated by Young. When these were superposed the original colours of the object were reproduced, save for the defect that the red and green components suffered from the insensitiveness of the photographic plate of Maxwell's time to the longer wave-lengths. Maxwell added the remark that when the photographic plate was improved as regards sensitiveness to the less refrangible rays, the representation of colour would be improved.[2]

Since Maxwell's day the colour blindness of the plate has been almost completely remedied, thanks to the discovery of Vogel, and it is now possible, proceeding on the lines laid down by Maxwell, to produce by triple projection upon the screen a picture which may be illusively like nature. For the application of modern resources and the suggestion of photographing to the colour vision curves by special colour screens, we have to thank Mr. Ives.

Composite colour photography deals with the subjective reproduction of all visible wave-lengths in two stages; a photographic analysis and an optical synthesis. In the first operation the several wave-lengths are caused to produce three separate photographic images according to their physiological activity in exciting the supposed fundamental red, green, and violet sensations. That is, if the image bears, for example, a yellow colour (suppose such a yellow as the spectral yellow near the D line), one of the plates must record an image of the object having a density of silver deposit corresponding to the degree in which this wave-length can excite the red-seeing nerve, and a second must acquire a density corresponding to the degree in which this same wave-length can excite the green-seeing nerve. The third plate records no impression, for the wave-lengths near D excite no violet sensation; but this yellow sensation is the resultant of two physiological effects only, a red and a green sensation in certain proportions obtained by colour measurements effected upon normal colour sight. We have now obtained three negatives possessing densities of silver deposit corresponding to the degrees in which the three several fundamental colour sensations are stimulated. These degrees of density will be interpreted as degrees of transparency in the positives. The first positive, if backed with a red glass, will transmit a quantity of red light corresponding to the intensity of the physiological excitation of redness in the "red" nerves; the second, backed with green, similarly represents the stimulation of the "green" nerves by the yellow colour of the object; the third positive is backed with blue-violet glass, but is quite opaque, and no violet light is transmitted through it. The projection now of all three images superposed upon the screen forms the second stage of the procedure; the optical synthesis of the original colours. The eye regarding the superposed image receives, in fact, the same amounts of red and green sensation, and experiences the same absence of violet sensation which would have attended the formation of the image of the original object upon the retina.

This process, if accurate reproduction of colour is sought, necessitates the use of two distinct sets of colour selective screens; for the analysing screens will by no means possess the tints ultimately required in the optical synthesis. This is evident since the measurements on colour vision reveal that the wave-lengths near D are more strongly stimulative of red sensation than are the purely red exciting wave-lengths near C, and the wave-lengths again diminish in their power of producing stimulation of the "red" nerves on the more refrangible side of D. Hence, in order to photograph the wave-lengths of the spectrum, we require to produce a greater photographic effect by the D wave-lengths than by the C wave-lengths, and a photographic

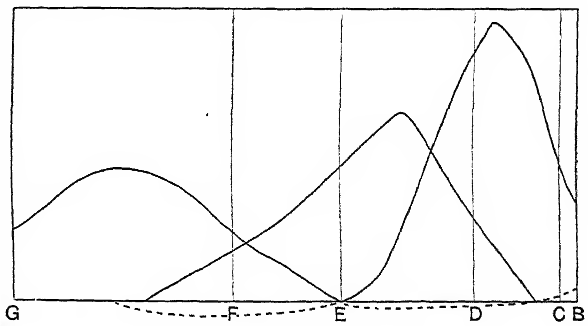

FIG. 1.

effect diminishing above D in the same degree as the power of the waves to excite the fundamental red sensation diminishes. To effect this analysis of the light a screen transmitting as predominant wave-length, a wave-length near D must be used for obtaining the image which is to represent the appreciation of light peculiar to the "red" nerves. Such a screen has a yellow-orange colour, which is not the sensation excited in or transmitted by the "red" nerves. In the optical synthesis this must afterwards be represented by a C red colour. The same remarks apply to the other screens.

Maxwell's curves (Fig. 1) are not colour sensation curves (Abney: "Colour Vision," Tyndall Lectures, 1895), and it is misleading to speak of the foregoing method as effected on colour sensation curves. Maxwell's curves represent, in fact, the subjective synthesis of the spectrum out of three chosen wave-lengths—a red, a green, and a blue-violet. The question as to how far one or all these chosen wave-lengths may excite more than the one set of nerves remains over, and indeed can only be gone into by examination of abnormal colour vision. In Kœnig's curves of colour vision, colour sensations are plotted. These are shown in the named curves of Fig. 2.

If, from the knowledge afforded by Kœnig's curves of the compound nature of the green sensation, Maxwell's curves be examined with reference to their suitability to serve the purposes of the photographic method, it will be found that, assuming Maxwell's E green to excite the proportionate amounts of red and violet sensation revealed by Kœnig's curves, a correct synthesis of the F green by Maxwell's curves is impossible. Although such a comparison is not strictly allowable owing to

[1] Abstract of a paper read before the Royal Dublin Society, by Dr. J. Joly, F.R.S.
[2] "On the Theory of Three Primary Colours." "Collected Papers," p. 449.

the red and violet curves of Maxwell being based on different wave-lengths to those used by Kœnig, the fact of grave inaccuracy is certain. This fact will appear if the spectrum is photographed according to Maxwell's curves. The blue-green will then be found to be reproduced too yellow in tone.

In order to apply the colour sensation curves of Kœnig to the photographic method, we have to find by trial examinations of his curves the green most suitable for backing the "green" positive; for we see that the several green wave-lengths excite very different amounts of red and violet sensation. We find as suitable a wave-length a little to left side of the E line, about 550 $\mu\mu$. If we take this colour to back the green positive, we must, in order to find the correct red and violet curves which are to control the densities of the red and violet images, replot the red and violet curves with allowance for the proportionate amounts of red and violet which will be carried to all those points where in the image of the spectrum the green curve operates. The red and violet curves must be lowered by amounts obtained by ascertaining from the height of the green curve at any point the amount of red and violet sensations excited by the amount of our selected green present at that point. The final curves are shown in the slightly altered violet sensation curve, the original green sensation curve, and the considerably lowered red-mixture curve (as it may be called); the full line in all cases representing the applicable curves. It is seen that the amount of negative colour (which cannot be realised) is small. Although it is possible that the compound nature of our green sensations will deny absolute accuracy to this method of colour photography, still my own results on the curves just described, and the results of Ives and others on modified Maxwell curves, appear to show that a degree of accuracy baffling the criticism of the ordinary untrained eye may be attained, and that in the reproduction of the most complex tints.

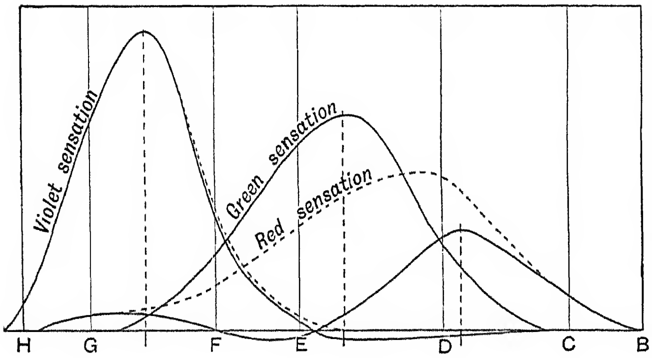

FIG. 2.

The symmetry of the derived curves renders their application easy. The transmission of light through a pigment is not limited generally to a small group of predominant wave-lengths, but falls off uniformly at either side in the directions of longer and shorter waves. If we choose the pigments used on the analysing screens so that their predominant transmissions are at three points in the spectrum indicated by the axis of symmetry of the three curves, these being nearly symmetrical, very accurate results are obtained. The positions of these axes of symmetry are shown by the vertical dotted lines. Accordingly, I make the colour of the red-taking screen that of the spectrum at a point displaced to the red side of D by about one-sixth the interval D to C; for the green and violet-taking screens the correct tints are found in the same manner by scaling from the figure. Good results are thus obtained, but I do not assert that these details of procedure are final.

Any method of photography in natural colours must possess the characteristics not only of accuracy of colour rendering, but also of convenience of application and permanency of colour, if it is to possess value as a scientific method. For use under the various circumstances of travel the naturalist requires a method no more cumbersome than the present dry plate. In the method of composite colour photography, as described, the ordinary camera will not serve. The cumbersome necessity of obtaining three images remains, and subsequently no concrete image in natural colours is actually obtained. One can only be realised by triple projection upon a screen, or by using some optical contrivance which, by the aid of reflectors, enables all three images to be simultaneously projected upon the retina.

I now proceed to describe a mode of applying the foregoing principles which is free of the objection of cumbersomeness, and which enables us to realise a concrete image in transparent colours. A plate is finally produced which may be held in the hand, regarded against the light, and which bears an image of the object in natural colours, or such as are so nearly accurate as to seem so to the eye. In this new method there is but the one image photographed. The ordinary camera, lens, and backs, &c., are used without modification. The first-class isochromatic plates in the market, which are sensitised down to the C red, will give very good results.

In the new method the idea is to carry the application of physiological principles still further, and divide up the plate like a hypothetical subdivision of the retina, so that all over the plate there should be minute regions uniformly distributed wherein the sensitive silver salt is excited to become reduced to the "photogenic" material in the same degree in which the sensations of redness, greenness, violetness, would have been actually excited in the several nerves of the retina had the image been formed upon it. Development builds upon this photogenic material the denser silver deposit, and ultimately in the positive the amounts of the sensations are registered in the degrees of transparency of the successive regions. The lined screen which can bring about this I can show you in the microscope. It consists of closely ruled adjacent lines in orange, green and violet tints. This screen, applied closely to the sensitive surface, analyses the image in the camera. The screens I have used hitherto are coarse, about 200 lines to the inch, and even with this coarseness will show plainly, I regret to say, the imperfections of the only apparatus at my command in preparing these screens. I may observe, in passing, that the colours are ruled on in pigments made up as inks in gelatine and gum arabic or dextrine, and upon plates coated with a preliminary layer of gelatine. Such lines may be put on so close as 800 or 1000 to the inch. With between 300 and 400 to the inch, however, the eye is no longer annoyed by the structure of the plates. The lines may also be ruled on celluloid or on translucent paper.

The appearance of both negative and positive obtained is interesting. One would hardly at first sight distinguish between them and the ordinary images. But a lens readily shows the difference. Recalling now that the lines upon the positive register in their degrees of transparency the degrees in which the three-colour sensations would have been excited, it becomes apparent that to complete the physiological parallel we must convert these degrees of transparency to quantities of the red, blue and violet colour sensations. This is done by a second screen, which carries red, green and violet lines to the same gauge as the taking screen. We apply this to the positive, and as we move it over the image, waves of every tint of colour appear till that position is reached where the red lines fall over the lined areas recording red sensation, and so for the others. The picture now suddenly appears in vivid colour and with all the realism and relief conferred by colour perspective.

A picture of wallflowers taken through a dichromatic screen, the red and green sensations only being photographed, is of interest as realising the appearance of the object to a violet-blind eye. The rich reds and browns appear unaffected; the greens are, however, somewhat unnatural. A photograph of the spectrum shows the range of colour from the C red to the H lines. The blue-green is, however, defective. It was taken according to Maxwell's curves. Photographs of burnished metallic objects, as a brightly lacquered microscope, reproduce the metallic lustre; and one of an uranium glass bowl, reproduces the characteristic dichroism and fluorescent appearance of the glass when seen by daylight. That every shade of colour can be reproduced, however complex, is shown by two portraits, one from life, and one a copy of a water-colour drawing boasting very æsthetic shades of brown and olive. A great variety of bright sunlit colours appear in a view at the Trinity College athletic sports, wherein the scarlet uniforms of the military band, the green of the grass, and the blue sky, recall the vivid appearance of the image on the ground glass screen of the camera. The colour perspective in such pictures adds greatly to the reality and relief. The faithful reproduction of texture, as in the case of some pansies, where the velvety browns and purples of the originals reappear, or as in the case of the wallflowers, reminds us how much is

inferred from the most subtle differences of light and shade in the colours of objects, in association with previous experience derived through other senses. The picture is always an optical illusion; and this additional illusiveness conferred on the photograph by the method invented by Maxwell on the basis of the three-colour theory of vision, is surely a strong confirmation of that theory.

These results are attained by no new photographic operations. It is necessary to use good orthochromatic plates sensitised into the red, and also to have affixed in the lens an orthochromatic screen cutting of the ultra-violet light in the usual manner. The exposure is somewhat longer than the ordinary exposure, for we can of course only use visible light, and of this a part is stopped by the taking screen. The ordinary backs may be used. The displacement of the sensitive film from accurate register with the ground glass camera screen, owing to the presence of the taking screen in front of it, may be corrected (if thought necessary) by simply reversing the surface of the ground glass camera screen, turning the muffled side outward. This secures that the image will be accurately focussed in the plane of the sensitive surface. Negatives and positives may be used as ordinary negatives or positives till it is desired to recall the original colours. Thus, for those who wander with the camera, the possession of but the one seeing screen to test results is sufficient, and of course the one taking screen suffices to take an indefinite number of plates.

These considerations lead us naturally to observe that the registration of colour being really carried in the silver image, which with very little care in manipulation may be made permanent, secures that the colours are permanent. A faded screen may at any time be made good by a fresh screen; the colours in all cases being spectroscopically chosen, we are assured of the reproduction of the original colour. In this aspect the necessity of the detached colour screen is no disadvantage, but rather a necessary safeguard against the inevitable fading attending most pigment colours.

COMET MAGNITUDES.

Dr. Holetschek, of the Vienna Observatory, has recently communicated to the Imperial Academy of Sciences a paper on the magnitude and brilliancy of comets and their tails, with the view of arranging them in "magnitudes" or orders of brilliancy in a manner similar to that in which stars are arranged according to their lucidity. Further, from the data given as to the apparent length of the tail, the true length of the tail has been computed, and an inquiry instituted as to the possibility of tail formation and its probable length, based on the resulting magnitude of the comet and its perihelion distance.

If it be true that the brilliancy of a comet varies as the squares of the distances from the sun (r), and from the earth (Δ), then from observations made at various points of the orbit, the same "magnitude" ought to result for the values $r = \Delta = 1$. This magnitude Dr. Holetschek has deduced, where sufficient data existed, and the results can be practically arranged in two classes: one, in which the deduced magnitudes derived from various values of r and Δ so nearly agree that a mean can be taken; the other, in which is shown a regular progress, and always in the direction that the deduced magnitudes with small radii vectures, therefore when the comet is near perihelion, are greater than when at large distances from the sun. The origin of this is due to the fact that the second power of the radius vector does not fully represent the variations occurring in comets as they approach the sun, at which time their brilliancy is more increased than is shown by the ratio $1 : r^2\Delta^2$. The first case, it is suggested, is only a special case of the second, arising through insufficiency of description. This is most clearly shown when the time covered by the observations is short, or the details so wanting in accuracy that the deviation from the ratio $1 : r^2\Delta^2$ cannot be known with certainty. The conclusion drawn is that the formula so generally used can represent the brilliancy of a comet at different distances from the sun for a short time only, and is inapplicable for long periods.

Dr. Holetschek uses the deduced magnitude in the neighbourhood of the perihelion, valuable as showing the greatest brilliancy attainable in a particular comet, as the data for forming the comets into orders of magnitude, and inquires how far the tail formation is connected with this magnitude and the perihelion distance. He decides from his material, that when the deduced magnitude is 6 or lower than 6, only a short and feeble tail, or one not visible to the naked eye, is possible. Comets with a deduced magnitude of 4, or still brighter, have a tail well visible, which is the greater, the smaller the perihelion distance, and the smaller, the greater this distance. Within the limits between 4 and 5 magnitude, if we exclude very great perihelion distances, lie the possibilities of a considerable tail development.

Dr. Holetschek has also considered the diameters of comets, and sought to introduce order by reducing the apparent diameter to that corresponding to a distance of the comet from the earth equal to unity. In the case of Halley's comet, no diminution or variability is to be detected in either its brilliancy or the length of its tail. The same values serve from 1456 to 1835. As, however, on account of the continual development of the tail, a diminution of the mass is probable, it cannot be decided whether the approximate constancy, shown in the investigation, arises from inadequacy in the observations themselves, or is produced by certain processes existing in cometary bodies.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The delegates of the Common University Fund have elected Mr. Edwin Stephen Goodrich, Merton College, to the Biological Scholarship at Naples for the year 1895-96.

Cambridge.—The report to the Senate of the Engineering Laboratory Syndicate, dated November 9, 1895, is a very satisfactory record of energetic work. The University was unable to provide more than £1000 for the building and equipment of the laboratory, which was estimated to cost about £6000. By steady and enthusiastic efforts Prof. Ewing and his colleagues succeeded in collecting from many sources, within and without the University, the £5000 that were needed; and what is still more to their credit, have completed the work in hand with a small balance to the good. The continued growth of the department, in which there are now eighty-five students under instruction, makes a further extension of the buildings urgently necessary. A site has been provided for the purpose, but further funds are needed for construction. The workshops, never intended to be other than temporary, must soon be rebuilt, and more lecture-room accommodation must be provided. The department has certainly justified its existence, and the Syndicate have proved themselves to be worthy stewards of the funds placed at their disposal. It is to be hoped that, with these guarantees that they will be well used, the needful moneys may ere long be forthcoming. The valuable services of Mr. Dalby and Mr. Lamb, the demonstrators of mechanism and engineering, in the work of organising the laboratory, are mentioned with cordial appreciation in the report. Among the donors of contributions of over £100 are the Duke of Devonshire, the late Earl of Derby, Mr. Frank McClean, and Dr. John Hopkinson, and eleven benefactors have given £100 each. Valuable donations of apparatus and of books have helped greatly towards the furnishing of the laboratory.

The amount, clear of all expenses, available for the Robertson Smith memorial, is £1450. It has been agreed by the subscribers that sufficient of this amount should be invested to produce an annual income of £30, such income to be employed on the continuance and extension of Prof. Robertson Smith's library, which he bequeathed to Christ's College. It was also resolved that the remainder of the amount collected, after all expenses have been paid, be handed over to the University for the purchase of Oriental MSS. for the University Library, which shall be marked as having been acquired by means of the fund. It is estimated that about £300 will be handed over to the Syndics of the Library.

It is reported that Mr. P. N. Russell has given the sum of £50,000 to endow a school of engineering in connection with the Sydney University.

An address on the present state and position of technical instruction in this country, delivered by Major-General Sir John Donnelly before the Society of Arts on Wednesday, November 20, is printed in full in the current *Journal* of the Society.

The annual meeting of the National Association for the Promotion of Technical and Secondary Education, and the Conference of Representatives of Technical Education Committees, will be held on Tuesday, December 10, at the Royal United Service Institution, Whitehall.

THE following announcements are made in the *Johns Hopkins University Circular* (No. 121):—Sir Archibald Geikie has accepted the invitation of the President and Board of Trustees of the Johns Hopkins University to inaugurate the George Huntington Williams Memorial Lectureship, and has selected October, 1896, as the time for delivering his lectures.—Prof. Cleveland Abbe, of the United States Weather Bureau, will, during January next, give four lectures upon Climatology in its relations to Physiography.—Mr. G. K. Gilbert, of the U.S. Geological Survey, will begin a course of lectures upon Physiographic Geology the second week in January, and will lecture four times weekly until about the end of February.—Mr. Bailey Willis, of the U.S. Geological Survey, will commence his lectures upon Stratigraphic and Structural Geology, as soon as Mr. Gilbert has completed his course, and wlll lecture twice weekly until the middle of May.—Dr. R. M. Bagg has been appointed assistant in Geology.

SIR JOHN GORST, in a speech delivered last Thursday at the annual meeting of the London Society for the Extension of University Teaching, remarked that "though they were all anxious that the scientific education of the country should be fully developed, it would be a great mistake if that development were to take place at the expense of the literary side of education. A proper liberal education is fairly balanced on all sides, and no system which extends one branch of education at the expense of others can be productive of anything in the long run but mischief." Just so. We have always urged that science should receive as large a share of attention as literature in our colleges and universities; but no one can say that it does. Some of Sir John Gorst's hearers took his remarks to indicate a reaction against the increased facilities now being offered for instruction in science; but if the remarks are taken literally, they mean that scientific education should be fostered, and placed upon the same footing as the humanities.

SCIENTIFIC SERIALS.

American Meteorological Journal, November.—Relations of the Weather Bureau to the science and industry of the country, by Prof. W. L. Moore, Chief of the Weather Bureau. It is satisfactory to find that the change of Chief will not affect the scientific activity of the U.S. Weather Office, as many people supposed. Prof. Moore quotes the Act of Congress of October 1, 1890, which prescribes the duties of the Chief, from which it is seen that the main object of the Bureau is to give warning of the approach of storms, and therefore that the proper line of investigation should be relative to their mechanism. Systematic exploration of the upper air, with a continuation of the studies of terrestrial magnetic forces, begun by Prof. Bigelow, will be the line of investigation prosecuted during the next two years. With regard to estimating the probability or severity of frost, Prof. Moore thinks that sufficient weight has not yet been given to the dryness or wetness of the soil, and he calls for special attention to this point —The meteorological observatory on Monte Cimone, Italy, by A. L. Rotch. Monte Cimone is the culminating point of the Northern Apennines, attaining a height of 7100 feet above the sea, and it is the only summit station in Italy, the observatories of Vesuvius and Etna being both situated on the flanks of these volcanoes. Both the summit and base stations are provided with self-recording instruments, and are dependent upon the Central Meteorological Office at Rome, with which there is telegraphic communication.—Physiological effects of high altitudes, by A. L. Rotch. The author points out the importance of the effect of the rarefaction of the air on the human system, which is, as yet, but imperfectly understood, and refers to his own experiences at great heights in the Alps and Andes.

Wiedemann's Annalen der Physik und Chemie, No. 10.—The practical use of Wheatstone's bridge, by F. Kohlrausch. The meter bridge is greatly improved and made more sensitive by introducing two resistances, 4·5 times the resistance of the wire, at one or both ends of it. The wire may also be rolled on a roller of marble or wood boiled in paraffin, with a flat spiral groove. With an enlarged scale reading to thousandths the author claims to have attained a limit of error of 1 in 25,000.—Density measurements of extremely dilute solutions, by the same author. These were made, as before, by weighing a glass sphere immersed in the liquid. But as the sphere used was heavier in this case, the cocoon fibre suspending it had to be replaced by a fine wire of dull platinum. The accuracy was then carried to the seventh decimal place, the only limit being the accuracy of temperature measurements.—Luminescence of solids and solid solutions, by E. Wiedemann and G. C. Schmidt. This is a continuation of previous researches on photo-luminescence and cathodo-luminescence, or the phosphorescence produced by the impact of light and cathode rays respectively on certain bodies, such as sulphates. A list of the most brilliantly luminescent substances is given, including "solid solutions," in van 't Hoff's sense, of $MnSO_4$ in other sulphates. The kind of luminescence of the latter depends only little upon the concentration, but much upon the kind of solvent. The lower the temperature the brighter the light. But the sulphates of copper, iron, and nickel extinguish it altogether, even in small quantities. The spectrum of the rays emitted is in every case a continuous spectrum consisting of one band.—On the absorption of cathode rays, by P. Lenard. The ratio between the absorptive power and the density is the same for all media, whatever their state of aggregation, provided the cathode rays are of the same kind.—Cathode rays and continuous discharges in gases, by O. Lehmann. This paper deals with the question of the actual nature of gas discharges.—The cooling effects of air currents, by A. Oberbeck. These are measured by finding what velocity of air is required to prevent the glowing of a platinum wire conveying a current. It is proposed to use this as a sensitive anemometer.—Anomalous dispersion curves, by A. Pflüger. Cyanine and Hofmann's violet have refractive indices below 1 for rays between F and G, and fuchsine, magdala red, and malachite green all show an increase of refrangibility with increase of wave-length in certain portions of the spectrum.

Bulletin de la Société des Naturalistes de Moscou, 1894, Nos. 3 and 4.—On the Ostracodes fauna of the neighbourhoods of Moscow, by A. Croneberg (in German). Twenty-three species are described, of which *Cyclocypris pygmæa* and *Erpetocypris peregrina* are new (with plates).—On the slates of Megalo-Aialo, near Balaklava, by D. P. Stremoukhoff (Russian, summed up in French). The presence of a number of Amonites, characteristic of the Bath and Kelloway strata, settles their age.—The birds of the government of Moscow, by Th. Lorenz. A list (in French) continued from a previous number.—The development of the tarsus in *Pelobatus fuscus*, by M. Chomiakoff (in German).—Two new Aphides from South Russia (*Stomaphis Graffii* and *St. macrohyncha*), by N. Cholodkovsky (in German) The microscopical structure of the electrical organ of the torpedo, by N. Iwanzoff, a large detailed work (in German), with plates in both numbers.—Yearly report of the Society.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 22.—Special meeting.—Captain W. de W. Abney, President, in the chair.—The following resolution, with reference to the articles of association, was passed. In Article 33, to strike out the words "by the payment of £10 in one sum," and in place of this to insert the words "the composition fee shall be, for every member who shall not have paid ten annual subscriptions, fifteen times the amount of the annual subscription payable by such member, and for any member who shall have already paid ten or more annual subscriptions, ten times the amount of the annual subscription payable by such member."—The ordinary meeting then took place.—Dr. G. Johnstone Stoney exhibited a print of Profs. Runge and Paschen's photograph of the spectrum of the gas obtained from clevite, together with a diagram illustrating the manner in which these observers have arranged *all* the lines obtained in two sets, each set containing three series of lines. Dr. Stoney also drew attention to the resemblance between each of these sets of three series of lines and the similar triple series obtained in the case of the metals of Mendelejeff's first group. The lines of the different series in the case of the gas obtained from cleveite have certain definite peculiarities which permit of their identification and selection. The two gases, to the presence of which the two sets of lines are presumably due, can be partly separated by diffusion through a plug of asbestos. Prof. Ramsay's observation that by suitably altering the pressure of the gas the predominance of the lines in either of the two sets can be increased is, however, against the

theory that the two gases are really separated by diffusion. Three of the original negatives taken by Prof. Rowland when preparing his map of the solar spectrum were also exhibited. Dr. Gladstone said he had examined the spectrum of the gas in two tubes, one of which had been filled by diffusion through an asbestos plug, and the helium line (D_3) was certainly brighter in one tube than in the other, though the brightness of the remaining lines appeared about the same in both tubes. As to the difficulty of allocating the new gases in Mendelejeff's table, it appeared to him (Dr. Gladstone) that they would have to be put in the first group between hydrogen and lithium. An examination of the successive differences between the atomic weights of ad jacent members of the metals in the first group showed that these differences increased as we go downwards. If then the new gases have atomic weights of, say, 2 and 4, we should have for these differences 2, 2, 3, 16, 16, 26, &c., instead of 6, 16, 16, &c., as at present. The important point which required investigation was whether these two gases were really simple bodies or not. Prof. Silvanus Thompson asked if Runge and Paschen had performed a similar analysis of the lines in the spectra of other elements besides the members of the first group. He would also like to know if in the case of any element besides hydrogen the lines could be arranged in a single series. Dr. Stoney, in reply, said that the spectra of most of the metals had been analysed, the chief exceptions being iron, nickel, cobalt, and manganese. There was no other element besides hydrogen which gave a single series of lines. Prof. Herschel gave an account of a line of reasoning which had led him many years ago to a formula resembling that expressing Balmer's law for the hydrogen lines, namely, $\frac{1}{\lambda} = 1 - \frac{4}{n_2}$. The Chairman (Captain Abney) drew attention to the fact that Runge expressed his result to 1/1000th of an Angström unit, although Dr. Stoney had said the measurements could only be made to within 1/50th of a unit. There was great lack of uniformity in the method of drawing spectra in general use; he strongly recommended the placing of the red end of the spectrum to the right, so that the wave-lengths increased from left to right. As to the three series of lines obtained in the case of most elements, it was not conclusively proved that they were not due in each case to three distinct kinds of molecules, and it will probably be found that there are more than two simple gases present in the gas evolved from cleveite.—Mr. R. Appleyard read a note on the action of sulphur vapour on copper. When a copper wire is exposed for some time to the action of sulphur vapour, it becomes entirely converted into sulphide of copper, and it is found that there is a fine axial hole running down the rod of sulphide formed. Rods of copper of square section cut from a block of copper after exposure to the action of sulphur vapour also exhibited the axial hole, the rod of sulphide formed being of circular cross-section. In every case the diameter of the rod of sulphide is about twice that of the original rod of copper. Delta metal was found to be unacted upon by the sulphur vapour.—Mr. Appleyard then read a paper on a "direct-reading" platinum thermometer. This form of platinum thermometer has been devised with the view of determining the temperature of the dielectrics employed in some experiments on the variation of the electrical resistance of dielectrics with temperature. The thermometers consist of six platinum coils, each of about seven ohms resistance, attached to thick copper leads. A slide-wire Wheatstone's bridge is employed to measure the resistance. The stretched wire is three metres long, and the moving contact so arranged that it is impossible to damage the wire. The auxiliary coils used in connection with the bridge are immersed in a bath of paraffin oil, the temperature of which is maintained constant, and a little above that of the air, by means of a glow-lamp immersed in the oil. Mr. Appleyard also read a historical note on resistance and its change with temperature, in which he showed that the earliest measurements of the variation of resistance with temperature were made by Lentz in 1833. Some experiments on this subject made by Davy were also referred to, and some of these experiments repeated before the Society. Mr. Trotter said he agreed with the author, that the "reserve of precision" at our disposal, on account of the delicacy of some of the modern instruments, ought to be made use of to facilitate the rapid performance of many measurements where the utmost accuracy is not necessary. He had the impression that platinum silver was not now considered the best material for use as the bridge wire. Mr. H. F. Burstall explained the differences between the temperature as measured on the mercury, air and platinum thermometers. At a temperature of about 40° the platinum thermometer read about 0°·4, and the mercury thermometer about 0°·1 below the air thermometer. Prof. Callendar had obtained measurements of temperature correct to within 0°·1 by using a Weston voltmeter and an ordinary Wheatstone bridge the variations of resistance, and hence the temperature being read directly from the deflections on the voltmeter. Mr. Rhodes thought that, except where extreme accuracy was necessary, the mercury thermometer was very much more convenient than the platinum thermometer. Mr. Burstall said the great convenience of the platinum thermometer lay in the fact that the scale could be read at a distance of many yards from the point where the temperature was being measured, and hence could be used in many places where it would be impossible to read a mercury thermometer. Mr. Blakesley considered that the author was somewhat bold to state that for general purposes it was never necessary to measure temperature to nearer than one-tenth of a degree. The author having replied, the Society adjourned till December 13.

Mathematical Society, November 14.—Major MacMahon, R.A., F.R.S., President, in the chair.—The President announced the death of Mr. E. H. Rhodes (elected June 10, 1875), which took place on the 1st inst —The gentlemen, whose names were published in NATURE of October 31, were, after the ballot had been taken, declared duly elected on the Council for the ensuing session.—The President stated the reasons which had led Mr. M. Jenkins, after thirty years' tenure of the office, to resign his position of Secretary, and moved a vote of thanks to that gentleman for his "devoted services of thirty years" to the Society, and coupled with the vote the hope that his health might be improved by his retirement to the country. The vote was seconded by Mr. Kempe, F.R.S., and supported by Mr. S. Roberts, F.R.S., who had been connected with the Society almost from its inception. After the vote had been unanimously carried, Mr. Jenkins suitably thanked the Society and the speakers for their good wishes and appreciation of his services. The following papers were read or communicated: On the stability and instability of certain fluid motions (iii.), and on the propagation of waves upon the plane surface separating two portions of fluid of different vorticities, by Lord Rayleigh, Sec. R.S. The two earlier papers upon the subject of these communications are to be found in the Society's *Proceedings* (vol. xi., 1880, and vol. xix., 1887).—Determination of the volumes of certain species of tetrahedron without employment of the method of limits, by Prof. M. J. M. Hill, F.R.S. Proofs are first given of the propositions: (A) that it can be shown without dissection that symmetrically equal tetrahedra are equal in volume. (B) That two tetrahedra having a common base, and being the images of one another with regard to that base, are equal. (C) That a tetrahedron, in which the line joining the middle points of two opposite edges is perpendicular to those edges, can be bisected into two superposable tetrahedra by a plane through either of these edges and the middle point of the other. By means of (B) a tetrahedron of special form is constructed, such that a prism can be built up of this tetrahedron and two of its successive images. The volume of this species of tetrahedron is then known without employment of the method of limits. Calling it ABCD, its sides are expressible in terms of two parameters a, r as follows:

$$AC = a\sqrt{9 - 3r^2}, \quad AD = BC = 2a,$$
$$AB = BD = DC = a\sqrt{1 + r^2}.$$

By means of (C) two other types of tetrahedra, whose sides are expressible in terms of two parameters, are deduced from the tetrahedron ABCD. Also by a consideration of a special case of the tetrahedron ABCD, the volumes of two tetrahedra of definite shape, not included in the above-mentioned types, are determined.—An extension of Sylvester's constructive theory of partitions, by the President. In connection with this paper the President communicated a paper by Prof. Forsyth, F.R.S., entitled, "Some algebraic theorems connected with the theory of partitions.' The paper is concerned with a general method leading to the proof of some theorems required in Major MacMahon's investigations in the partitions of numbers. They depend upon the summation of terms selected from the series, which is the expansion of particular fractions, and the summation is effected algebraically.—On the evaluation of a certain dialytic determinant, by Mr. W. W. Taylor. In a paper read before the Society in March 1894, Prof. Elliott (the author) remarked: "It

is unfortunate for the simplicity of the argument of this paper that the property of such a determinant as Δ, that after division by its obvious factors $F(\rho, 1)$, $F(\rho, -1)$, it leaves a perfect square, is one which, as far as I know, direct algebraical methods have not yet supplied." This *lacuna* Mr. Taylor supplies.—Lieut.-Colonel Cunningham, R.E., communicated a criterion of 2 as a 16^{ic} residue, and added some remarks upon certain of Mersenne's numbers.—The following papers were taken as read: Notes on matrices, by Mr. J. Brill; certain general series, by Mr. F. H. Jackson; note on the representation of a conic by a linear equation, by Mr. J. Griffiths; on the representation of a number as a sum of two squares, by Prof. G. B. Mathews; researches in the calculus of variations: part vii., limiting conditions in multiple integrals; part viii., reduction of the problem of the discrimination of maxima and minima values in double integrals with variable limits to a new problem in single integrals, by Mr. E. P. Culverwell; a note on certain forms of the equation of normals to conic sections, by Mr. J. L. S. Hatton.

PARIS.

Academy of Sciences, November 18.—M. Marey in the chair.—Truffles (*Terfezia hanotauxii*) from Teheran, by M. Ad. Chatin. The characteristics of Persian truffles and their spores are described. The name *Terfezia hanotauxii* is given to these truffles as forming a new species. The most important characters are given for comparison of the other known species of Terfezia: *T. claveryi*, *T. boudieri*, *T. hafizi*, and *T. leonis*.—On a probably new element existing in the terbium earths, by M. Lecoq de Boisbaudran. The evidence relied upon is that of an absorption band at λ 487·7, which the author fails to connect with known elements.—A memoir, by M. A. Sarrat, on a demonstration of Fermat's theorem. Impossibility of the equation $a^n + b^n = c^n$ in whole numbers, was submitted to a committee.—A note of M. J. Laborde on the causes of the formation of hail was similarly disposed of.—Observations of the sun, made at Lyons Observatory (with the Brunner equatorial) during the second quarter of 1895, by M. J. Guillaume.—On the employment of punching and shearing as methods of testing metals, by MM. L. Bacte and Ch. Fremont. A machine, called by the authors an *elasticimètre*, is described by means of which indicator diagrams are obtained which show the actual character of the instantaneous stresses developed in the operations of punching and shearing. Special test-samples are not required, the machine is applied while the material is being worked up in the ordinary way.—On a power dynamometer specially applicable to physiological studies, by M. Charles Henry.—On the origin of atmospheric oxygen, by M. T. L. Phipson. The author recalls the results of his researches on this subject, and summarises them as follows: (1) In the most distant geological periods nitrogen formed, as now, the principal part of the earth's atmosphere. (2) The presence of free oxygen in this atmosphere is entirely due to vegetation. Primitive plants were the means by which oxygen was naturally supplied to the air. (3) Plants now living are, like those of geological times, essentially anærobic. (4) As the quantity of free oxygen in the atmosphere has gradually augmented, the anærobic cell has become modified into more or less ærobic forms (fungi, bacteria), and finally has become completely ærobic (in animal life). (5) The lowest unicellular algæ give, weight for weight, much more oxygen to the atmosphere than to the superior plants. (6) In proportion with the slow increase of the relative quantity of oxygen in the air, the cerebro-spinal nervous system, the highest characteristic of animal life, has become more and more complex.—Synthesis of methyleugenol. Constitution of eugenol, by M. Ch. Moureu. Allyl veratrol is synthetically formed and shown to be methyleugenol. It follows that eugenol is an allylguaiacol.—On the cholesterines of the cryptogams, by M. E. Gérard.—On the distribution of pectase in the vegetable kingdom and on the preparation of this diastaste, by MM. G. Bertrand and A. Mallèvre. Pectase may be regarded as of universal occurrence in the green plants. It is especially abundant in leaves, and probably spreads from the leaves to the other organs. The richness of certain leaves in pectase has permitted the preparation of this ferment.—Researches on the Tapidæ, by M. Piéri.—Study on the reproduction of wasps, by M. Paul Marchal.—On a morphological modification of species and on the heredity of acquired characters, by M. Rémy Saint-Loup.—On a disease of the sloe-tree contracted spontaneously by a maple, by M. Paul Vuillemin.—On the structure and optical properties of divers compact or earthy silicates, by M. A. Lacroix. The minerals studied, though apparently compact and earthy, are formed wholly or in part of a crystallised substance having many of the properties of mica.—On the optical isomorphism of felspars, by M. Fr. Wallerant.—Triassic ammonites from New Caledonia, by M. Edmond de Mojsisovics.—On the retting of flax and the microbe concerned, by M. S. Winogradsky.—On the use of viper's and adder's blood as antivenomous substances, by MM. C. Phisalix and G. Bertrand.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—A Manual of Physics: Dr. W. Peddie, 2nd edition (Baillière).—Thirteenth Annual Report of the Fishery Board for Scotland. Part 3. Scientific Investigations (Edinburgh, Neill).—Mechanics, Hydrostatics: R. T. Glazebrook (Cambridge University Press).—Cambridge Natural History. Vol. v. Peripatus, Myriapods, Insects: A. Sedgwick, F. G. Sinclair, and D. Sharp (Macmillan).—Molecules and the Molecular Theory of Matter: A. D. Risteen (Ginn, Boston).—On the Densities of Oxygen and Hydrogen, and on the Ratio of their Atomic Weights: Dr. E. W. Morley (Washington).—Elementary Inorganic Chemistry: Prof. A. H. Sexton, 4th edition (Blackie).—Earth-Knowledge: W. J. Harrison and H. R. Wakefield, Part 1, 9th edition (Blackie).—Food and its Functions: F. Knight (Blackie).—Minerals and how to Study them: E. S. Dana (Chapman).—Grundgesetze der Molekularphysik: T. H. Schwartze (Leipzig, Weber).—Sur l'Origine du Monde: H. Faye, troisième édition (Paris, Gauthier-Villars).—Essais sur la Philosophie des Sciences. Analyse-Mécanique: C. de Freycinet (Paris, Gauthier-Villars).—First Stage Mechanics: F. Rosenberg (Clive).—Observaciones de Precision con el Sextante, Conde de Cañete del Pinar (Madrid, R. Alvarez).—The Wild Fowl and Sea Fowl of Great Britain: A Son of the Marshes (Chapman).

PAMPHLETS.—Cantor Lectures on Commercial Fibres: Dr. D. Morris (Trounce).—An Account of the Smithsonian Institution (Washington).—The Exhibit of the Smithsonian Institution at the Cotton States Exposition, Atalanta, 1895 (Washington).—Christian Huygens: J. Bosscha (Leipzig, Engelmann).—The Common Crow of the United States: W. B. Barrows and E. A. Schwarz (Washington).

SERIALS.—Natural Science, December (Rait).—Longman's Magazine December (Longmans).

CONTENTS.

THURSDAY DECEMBER 5, 1895.

THE ORGANISATION OF SCIENCE.

As we are accustomed in this country to look on the *Times* as a political barometer, the appearance in it of the very admirable article to which we drew attention last week must be regarded as proof that the exigency of the situation in which the nation is placed is likely soon to attract some share of the attention it imperatively demands. And the question arises how we may best secure that "scientific organisation in the field, in the workshop, in the laboratory, and in the conduct of national policy" which the *Times* so fully and justly recognises to be essential to our national safety.

It is just twenty years since the Royal Commission on Scientific Instruction and the Advancement of Science, presided over by the Duke of Devonshire—father of the present Duke—issued their final report in which they emphatically recommended the appointment of a Ministry and Council of Science. The report is full of evidence of a most convincing character, given by witnesses of the greatest eminence and wide experience; and when we recollect that it was signed by such men as the late Duke of Devonshire, Lord Lansdowne, Huxley, Sharpey, Henry Smith, Stokes, Bernhard Samuelson and Lubbock, it is more than surprising that its provisions should have been so completely neglected. In point of fact, and most unfortunately, nothing has yet been done to bring the State thoroughly into touch with science, and to lead it to regularly avail itself on all possible occasions of the services of qualified scientific advisers.

Had such a Council been called into existence, it would undoubtedly have operated in two ways. In the first place, its members would inevitably have had their attention drawn to public affairs, and the narrowness of purview which too often characterises the work and thoughts of men devoted to science, as well as of business men, would have given place to broad conceptions of civil duty, so that an ever-widening influence would have been secured to them. On the other hand, by gradually bringing about the introduction of scientific methods of regarding and treating State problems, they would have conferred inestimable service on the nation, and the growth of a system of rational statesmanship would have been encouraged. We are indeed able to form an effective estimate of what might have been the result of their labours—for, having commenced to organise our public service at about the same time, and pursued similar methods, we should not improbably have attained to a position comparable with that in which the Japanese appear now to be placed.

It would certainly have been impossible for the minister at the head of our educational affairs to gravely argue in 1895 in favour of granting to a small group of irresponsible individuals a post-card veto on the finding of a Statutory Commission, which his Government are begged to appoint to finally adjust the claims of the various parties concerned in the foundation of a University in London. Nay more, our minister would have been in a position to say that sheer force of circumstances compelled him to recognise that it was of the utmost national importance to immediately secure the effective organisation of all the higher educational interests of the capital of the empire—indeed, our Government would long since, at the instigation of its scientific council, have taken the matter into its own hands, and have brought about such organisation, instead of requiring to be positively compelled to act.

The existence of such a national council of scientific advisers—the words are used intentionally, as we are thinking of a council of men scientifically trained and of proved ability and originality—would infallibly have exercised a most potent influence on public opinion: in forming it and educating it. It would have spread abroad the spirit of inquiry by making it operative in every branch of the public service. The manufacture of red-tape would have fallen into oblivion instead of that of aniline dyes; agriculture would have been cared for, as it would have been foreseen that the lowering of freights, consequent on improvements in shipbuilding and the introduction of steam, made it necessary to relinquish wheat-growing into the hands of those who can command cheap labour and constant sunshine; and probably we should have learnt to make butter and grow onions at home.

Each of our public departments would have had a scientific staff, charged not merely with the duty of carrying out its routine work, but also expected to contribute to the growth of scientific knowledge, in order both to maintain touch with the outside world, and preserve and extend their interest in the subjects with which they were concerned. Only those can institute progress who themselves progress, and it is clear that this was fully recognised to be the case by the Duke of Devonshire's Commission, as it is stated in so many words in the report, that there was a general concurrence of opinion that, even in the interests of the Government Departments themselves, more ought to be done by the Government in the way of investigation.

The condition of our public service in these respects is nothing less than deplorable, and yet, when the example set by Kew—which, during many years past, has always been in the hands of highly-qualified scientific administrators—is taken into account, the advantages to be derived are so obvious. Where are the scientific men connected with our great departments of national defence in evidence? Most important researches on explosives have issued from Woolwich in days gone by; and Froude's great work under the Admiralty was epoch-making. What is being done at the schools where naval and military officers are being trained to make an atmosphere of research not only possible but essential? And when we pass to our colossal Indian empire, what is being done there to encourage the growth of the scientific spirit among those concerned in the administration of its affairs? We believe that at the present moment there is but a single agricultural expert available for the whole of India, and yet agriculture is the one industry on which the country is practically dependent. Why is engineering considered to be the only branch of science worthy of introduction into the public service?

As the present President of the British Association

said in his evidence to the Duke of Devonshire's Commission, "Our statesmen do not appreciate properly the value of scientific advice or scientific inquiry, and they are very much fonder of experiments made upon a large scale with no defined system, than they are of experiments which have been brought out as the result of a carefully studied previous inquiry." This is as true now as it was twenty years ago, and probably many hundreds of millions which might have been gained have been sacrificed in consequence.

The *Times* pointed out last week that, on his first appearance as Member for Foreign Affairs, M. Berthelot asked for money for the establishment of six new consulates in China. M. Berthelot may be properly described as the most original living chemist; he is certainly also the most prolific in ideas. As his Government will probably soon be thrown out in the natural course of affairs French, it might be well for us to consider whether a man who is capable of conceiving so daring an idea immediately on entering into political office might not—although a member of a class considered incapable of governing in this country—be invited over here to leaven our public service.

Reflections such as these should, however, give food for thought, not only to men of affairs, but also to those who are engaged in scientific work, and should lead the latter to ask themselves whether they are doing their duty in all respects—and this is especially the case at a time when we are seeking to appraise the value of Huxley's labours. Important as was his scientific work, and much as we are disposed to agree with Mr. Balfour as to the inestimable public service he rendered in making the doctrine of evolution plain and popular, the work he did in displaying the meaning of scientific method to people generally was, if possible, of even greater value. Yet how few follow his example—how few are prepared to be unselfish and to withdraw themselves from the fascination of their private investigations to labour in the cause which Huxley and also Kingsley made holy. If more had followed their example, we should now have far less cause to deplore the failure to apply scientific method in the public service which has led to the present break-down.

THE GROWTH OF THE BRAIN.

The Growth of the Brain. A Study of the Nervous System in Relation to Education. By H. H. Donaldson, Professor of Neurology in the University of Chicago. "Contemporary Science Series." (London: Walter Scott, 1895.)

THE "populariser" of science (who differs widely in kind from a Helmholtz or a Tyndall—the writers of popular science) labours under great disadvantages. He is compelled to give a scissors-and-paste account of the work done by other people in different departments, and to summarise a number of perfectly distinct monographs, omitting all the experimental evidence which alone gives value to the conclusions. He must not express any original criticism, and he usually has to bring in a moral. To say the best of it, he writes about science with an object, whereas science must be trodden for itself, like a Swiss mountain. It is a little sad to think that neurology is going to have an object—judging from the essay before us. It will become the lumber-room for histological details, weight statistics, architectural dimensions, a little physiology—very little—and some educational cobwebs to weave them all together. But such a collection should at least be up to date at the time it is offered to the public. An account of "localisation of cerebral function," with no reference to Munk and Goltz, no suggestion that opinions differ as to the extent of localisation, or that the expression "sensory *vs* motor" (tracts), has previously been termed "misleading," no hint that in the absence of the higher centres, function may be taken on by the lower, in any less long-suffering animal than the "brainless frog," does not lead one to anticipate much neurological pabulum.

The account of nutrition, again, is very inadequate; cell diffusion is referred to in almost purely mechanical terms, with little reference to the physiological activity of the epithelium. "Thyroid feeding," too, is casually introduced in a foot-note, with a couple of references to medical journals. Yet Brown-Séquard's name is not unknown, and we have lately heard a good deal about "internal secretion." Nor is the account of metabolism in the nerve-fibre very satisfactory. We are told that "it is possible to assume that there are metabolic changes which have not yet been detected, *or* that the nerve impulse is not accompanied by such changes." And again: "Physiologists have been busy at the same time seeking to determine how far the passage of a nerve impulse along a fibre causes fatigue-changes in it"; (no conclusion given).

Another loose statement is to the effect that the beat of the heart is an example of the automaticity of the nervous system. How then does it come about that rhythmic contractility appears in the embryonic heart before the nervous system has been developed?

Weismann has been assimilated, and is written out large for the "growth period of races and nations": so that, as Prof. Donaldson says, "the germ-plasm wears the appearance of immortality."

But we look in vain for any reference to recent French studies in experimental psychology, in which there is a fund of suggestion for "the parent, the teacher, and the physician," who are to "seek light" from the "facts within these covers." The question of types of perception—and of memory—is one of the most interesting in modern educational psychology. Instances are being classified every day of the visual, or auditive, or motor temperament; and surely we all know which is the particular language of our own translation of experience? Yet Prof. Donaldson can only suggest that "it is now recognised that thought can be carried on in terms of the several senses. In this connection Fraser (*Am. J. of Psychol.*, 1892) has made an examination of certain philosophic writers, which indicate that particular writers, or schools, prefer sense-images of one mode in their speculative thought, and he suggests that much of the failure to be mutually comprehensible depends on the fact that tactual and visual images, for example, are by no means capable of being manipulated in the same manner, and hence that relations conceivable in the terms of one are often not so in those of the other. With the employment of one sort of mental image comes precision; but it is precision gained at the price of limitations Fortunately

the law of the diffusion of incoming impulses works against a too great specialisation in this direction. Yet in the highly defective this specialisation must be carried very far, and in those whose endowments are distinctly unusual the dominance of one sense in controlling the reactions of the central system may rise to *the dignity of a deformity*." The last words should bring comfort to any poor victim of a temperament, but are a cheap substitute for the clear thought and scientific terminology of M. Binet or M. Ribot.

The account of consciousness and the relations between stimulation and sensation is also very defective. "Granting," we are told, "that the central system responds throughout a large extent to all the impulses acting upon it, and that by virtue of these responses the background varies; it remains to be determined how far the law and order in these changes can be formulated. . . . The reactions obtainable by the application of a given stimulus depend on the other stimuli with which the new one is competing. Cold water does not feel cold after ice; a black line on a grey surface has a value different from the same line on a white one, and so on throughout all contrasts. This relation between the stimulus and the sensation is expressed in the psycho-physic law by the formula that sensation increases in intensity according to the logarithm of the stimulus. The limits within which this law is applicable do not immediately concern us, its use here being purely to express the fact that at any moment the activities of the nervous system under the influence of existing stimuli *form a background against which a new stimulus, according to its intensity and character, may or may not be recognised*." (The italics are ours, here and elsewhere.)

The poverty of this conception of consciousness is typical of the whole book, which reads like a "background"—a dull record of facts with no living factors playing in and out of them, and making the physiological and psychological aspects into a conscious unity. It seems to have missed its mark, inasmuch as it is neither a scientific text-book nor a social philosophy.

F. A. WELBY.

THE VALLEY OF KASHMIR.

The Valley of Kashmir. By W. R. Lawrence, C.I.E. (Oxford: Frowde, 1895.)

UP till now the standard authority on Kashmir was Drew's well-known book. It contained a good deal of information about routes and passes, and concerned itself not so much with Kashmir proper as with the outlying and dependent territories. The present work has a more restricted aim, and deals more thoroughly with its subject. The reader must distinguish between Kashmir the kingdom and Kashmir the vale. The former is a large territory containing enormous mountain areas, chiefly uninhabited and stretching, in theory at any rate, from Tibet to Chitral and from the Pamirs to the border of the great Indian plain. But Kashmir proper is a level valley, apparently an old lake basin, included between a fork of the Himalayas. On the map it resembles, as Mr. Lawrence well remarks, a white foot-print set in a mass of black mountains. The level of the valley floor is about 6000 feet above the sea, and it is approximately 84 miles in length and 20 to 25 miles in width. Numerous trade-routes debouch upon this valley and concentrate upon its populous capital, Srinagar on the Jhelum. To Kashmir proper may also be reckoned the fertile lower portions of a number of tributary side-valleys, for the most part exceedingly beautiful, and well marked with wood, water, and meadow. This beautiful area—the garden of India—is shut off from the rest of the world by bare and, in many places, snowy mountain ranges, or by a gorge which has only a few years ago been trained to admit a cart road. It is inhabited by an interesting race, speaking a language and having a literature, a written history, and an art of their own. Thus Kashmir is marked out by nature, history, and circumstance as a geographical unit suited for separate treatment and study.

The Government of the Happy Valley was up till recently, in some respects, one of the worst in Asia. There was no security of property, and personal liberty hardly existed for the peasantry, who were liable to forced labour at any time of the year, however ruinous to their industry, and had to pay taxes to swindling publicans, equally disloyal to the tax-payer and to the State. To put an end to this state of things became a crying necessity. A survey and land-settlement was decreed, and entrusted to officials under British direction. The bulk of the work was done by Mr. Lawrence, who has been for some years the Maharaja's Settlement Commissioner, and by whom the whole transaction has been concluded. In his daily labour he has been brought in contact with all classes of the community, and especially with the peasants. He has been obliged to make himself familiar with the nature of soils, the systems of irrigation and agriculture, the character of the crops, the resources of the country generally, the system of taxation, the character of the official class concerned, and to deal with its collection, and all manner of similar and connected questions. In course of his work he has been forced to accumulate a large body of notes on these matters, and he was thus designated by circumstances as the man best suited to report on the condition and prospects of the country generally. I gather that the volume under consideration is practically the report, or the major portion of the report, drawn up by Mr. Lawrence for the Indian Government which placed his services at the disposal of the Kashmir Durbar.

The scheme of the report is drawn on large lines. There are chapters descriptive and historical. Others deal with the geology, physical history, flora, and fauna of the valley and its surrounding slopes. There is a chapter on archæology, another on statistics, whilst the remainder deal with the people, their races, languages, religions, manners and customs, industries, and trade, and with the old Administration and the new Settlement. Some of these chapters are admittedly compilations. That on geology is little more than a reprint of passages from Lyddeker's memoir. Less satisfactory is the archæological chapter, which chiefly consists of quotations from Sir Alexander Cunningham's reports—excellent at the time they were written, but now superseded by the work of excavation and research which is being done for the Indian Government by Dr. Stein. The chapter on the flora makes no profession of completeness, but, being contributed by experts, is authoritative as far as it goes. It is chiefly confined to "plants and trees possess-

ing some well-known economical value for the people." The fauna chapter is remarkable chiefly for its full list of the birds of Kashmir—a region very rich in birds—and here the author is able to introduce a number of original observations.

In the remainder of the book he writes as an authority of the first rank, and conveys a mass of new and admirably digested information. His contact with the people was evidently of a sympathetic character. The Kashmiri is usually not beloved by the European. His effeminate dress is against him, to start with. His moral and physical cowardice seem superlative. He appears to be fundamentally a liar and a cheat. Such, indeed, are too often the characteristics of the boatmen class with whom the traveller comes most in contact. But the Kashmiri *shikari* is of a finer sort, and many of them are well beheld by their employers. Mr. Lawrence explains that the truly typical Kashmiri peasant is really more of the latter type. He has vices, patent enough; but they are rather to be ascribed to the misgovernment, of which he has been victim for centuries, than to any original sin. The people are conscious of their degradation, and explain that it is the result of a curse from heaven, against which it is idle to protest. That curse Mr. Lawrence has done much to remove. In his quiet methodical fashion he has gone through the country with open eyes and healing hands. It is to be assumed that he went there to do a piece of work, and did it to the best of his ability, with no flaming ideals and high-sounding intentions. As a result, he has accomplished an amelioration in the lot of some hundreds of thousands of his fellow-creatures, great enough to warrant a less efficient founder of a new religion being raised to a pinnacle of eternal sanctity.

It is impossible within the limits of a brief review to give any idea of the volume and extent of work involved in the Settlement, and now actually accomplished. I was myself witness of some of its smaller fragments and effects. Still less can any idea be given of the value of the author's contributions to anthropology contained in this volume. He has entered into the life of the village and the cottage, and returned with note-books full of accurate and first-hand information. The greatest of his literary successes lies in the fact that he makes plain what a rich mine still remains to be worked. Here is folk-lore to be written down that would keep several men busy for years. Here is an important language to be studied. Here are customs of high antiquity yet remaining to be recorded and classified. It is to be hoped that Mr. Lawrence's book, besides bringing to him the high honour that is his due, and embodying a mass of most valuable facts and observations, will have a yet higher efficiency, in that it will get others to work along the lines, here laid down, to results yet more important and complete.

W. MARTIN CONWAY.

METALLURGICAL PROCESSES.

Metallurgy. An Elementary Text-book. By E. L. Rhead. (London: Longmans, Green, and Co., 1895.)

THE author's aim has been to present, within narrow limits, a clear and concise account of metallurgical processes, and he has done his work conscientiously, for much information has been included in the 271 pages of the volume, which also claims to be a "small handy book of reference.' This claim can, however, hardly be sustained, though the publication of the work is amply justified, mainly for the following reason. It is difficult to make the ordinary student of chemistry understand that metallurgical processes differ essentially from those he is taught in a chemical laboratory, for as regards "wet" processes the reactions which occur in large volumes of dilute liquids, held in tanks, are often more complicated than the chemical changes which may be studied with the aid of test-tubes or beakers. In dry processes also the student has to deal with problems which involve a knowledge of the influence exerted by mass and high temperatures, and his laboratory experience is often at fault. The sooner, therefore, that students are taught the need for special instruction in metallurgy the better, and a little volume like this one under review is to be welcomed, more especially as the author is careful to point out "that the equations given for reactions occurring at elevated temperatures only partially express the truth." He says that "details are only given when necessary for the sake of clearness"; and this reveals the weak point of his scheme. It is impossible to give details as to the extraction of individual metals from their ores in a book of this size, and it would have been better to have limited the range of the little volume to a consideration of the principles on which metallurgy is based.

There are several things which present themselves, even to a rapid glance through the pages, as needing change or modification. For instance, it is stated in the introduction that "a gold structure of the same strength as an iron one would be nearly nine times as heavy"; an illustration which is not very apt, as mere weight is not the only thing which prevents gold being used for constructive purposes. Standard gold would make a very fair gun, but it would be a costly form of armament. On p. 3, it is stated that "all metals, with the exception of chromium, have been reduced to a fluid condition by heat"; but chromium is no exception, as it is not difficult to fuse even the carbon free metal in the electric arc. Moissan has, in fact, shown that titanium is the least fusible metal known, though he succeeded in melting it. There is another use of the words "cold-short" than the one given on p. 4, for "cold-shorts"; and the student should be warned of this, as it is a point upon which an examiner would expect rigid accuracy. Turning through the pages, on p. 224 it is stated that during the roasting of certain silver ores the gold "is chlorinated, and thus dissolved out." This is practically not the case, though the mistake is not an unnatural one. The brief description, given on pp. 231–232, of hydraulic mining is very defective; the head is said to be "sometimes 200 feet," it really sometimes is as much as 500 feet. Somewhat ancient practice is described in relation to the stamp battery for crushing quartz. In describing the cyanide process for extracting gold, the author thinks that it would "displace the chlorination process if a cheaper method of making cyanide can be found"; but the progress of the very important McArthur-Forrest process has not, really, been in the least impeded by the cost of the cyanide. The reviewer has, however, been over-captious. He has persistently advocated teaching the methods of conducting

metallurgical processes by diagrammatic schemes such as the author has adopted; see p. 198, for instance. The one given for the blast furnace (p. 110) is certainly instructive.

The illustrations, of which there are nearly one hundred, are clear, but some of them are very old friends, while others are perspective drawings; and for a book like this, the reviewer would have preferred to see suggestive outlines and sketches, which the student could have transferred to his note-book with a few strokes of the pencil.

W. R.-A.

OUR BOOK SHELF.

Milk, its Nature and Composition; a Handbook on the Chemistry and Bacteriology of Milk, Butter, and Cheese. By C. M. Aikman, M.A., D.Sc. Crown 8vo. Pp. 173. (London: Adam and Charles Black, 1895.)

THE design of this little work is to give a short, popular statement of the more important facts concerning the chemistry and bacteriology of milk; and Dr. Aikman has succeeded admirably. A great deal of most valuable information is conveyed in a simple and eminently readable form, and it is a volume which is not only suitable for students in our recently started dairy-schools, but might well find a place in the library of any country-house. The general public is only very slowly awakening to the dangers which surround the consumption of dairy produce, and it requires the pressure of enlightened public opinion to produce the requisite reforms in the hygienic management of dairies. Dr. Aikman's volume, together with Dr. Freudenreich's "Bacteria in their relation to the Dairy," recently reviewed in these columns, should help a great deal in bringing about such reforms, which are not only of hygienic but of commercial importance to this country. In the section on the pasteurisation of milk, Dr. Aikman has overlooked an important fact, upon which the subsequent keeping power of such milk so largely depends, *i.e.* the *immediate* chilling of the milk after pasteurisation to a temperature below the point most favourable for germination. We think, in view of the recent valuable experiments, made in America and elsewhere, on the production of pasteurised milk on a commercial scale, and the importance of our adoption of a practice which has already gained considerable ground on the continent, Dr. Aikman might with advantage have entered more fully into this branch of the subject. Doubtless in a second edition Dr. Aikman will also expand somewhat the part devoted to cheese, and include some of the important and interesting results obtained by Bondzynski on the chemical composition of some varieties of cheese, published in the *Landw. Jahrbuch der Schweiz* last year. The illustrations accompanying the text are carefully chosen and well executed.

Elementary Physics. By John Henderson, B.Sc. (Edin.). Pp. 128. (London: Longmans, Green, and Co., 1895.)

IT may be well to remark at once that this is not a text-book of physics, but the first volume of a series of manuals designed solely for use in physical and electrical engineering laboratories. The present book is a general introduction to practical work in physics, and future volumes will be devoted to more advanced experiments. Altogether, eighty experiments are described, and are arranged in sections having the following succession: general physics, magnetism, electricity, heat, light, and sound. No serious attempt seems to have been made to connect the experiments in any particular order, so that, with few exceptions, they are independent of one another. A slight knowledge of physics is necessary before the student can understand and carry out the course of work described. This information may, however, be obtained from lectures given concurrently with the laboratory work, though the order of the practical course is not what most teachers follow in their lectures.

The experiments can be performed without any very elaborate apparatus, and we have no hesitation in saying that the student who works through them will by so doing obtain a sound knowledge of many important physical laws. The knowledge thus gained by direct observation is far and away better and deeper than that obtained by reading text-books.

Practical Trigonometry. By H. Adams, M.I.M.E. (London: Whittaker and Co., 1896.)

THE author of this small book is careful to point out that it is not a text-book; but it will be found useful to practical men, in enabling them to undertake the perusal of other than elementary works where a knowledge of trigonometry is essential.

The book is so arranged as to gradually disperse the difficulties to beginners in trigonometry, and it cannot but prove an incentive to further study. As an *aide-mémoire*, however, the absence of proofs, to secure brevity, will diminish its value for examinations where trigonometry is a special subject.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Remarkable Sounds.

WITH reference to Mr. McKenny Hughes' letter on this subject, which appears in your issue of the 14th ult., and to his suggestion that it "would be of great help if we would get some exact data as to the distance at which the sounds of great guns, of blasting, or of waves, can be proved to have been heard," I would ask permission to be allowed to cite my experience on the north coast of Spain at the fishing village of Comillas, about twenty-four miles west of Santander. The bay which gives rise to the port is relatively small, and of inconsiderable depth inland; the south-east part of it is limited shoreways by cliffs of limestone, which rise to a height of about 120 feet, and somewhat overhanging the base or water-line. When the ground-swell—so characteristic of the Bay of Biscay—comes in to this bay, the breakers are very remarkable, and dangerous for small fishing-boats, being relatively high, and succeeding one another with great regularity. They break against the cliff mentioned with a thundering noise, and such that I have frequently heard them at eight miles' distance inland, although high and uneven ground lay between me and the coast, and the weather was relatively calm, so that the sound could hardly be favoured in its transmission by the wind. In stormy weather, and when the weather has been bad seaward, then the waves are even more terrible, and the sound heard still farther away.

Dublin, November 27. J. P. O'REILLY.

IT is a pleasure to me to see Prof. Darwin's note on curious sounds, in NATURE for October 31, since I have often been puzzled by what is obviously precisely the same phenomenon along the Bay of Fundy coast of New Brunswick, particularly about Passamaquoddy Bay, where I have been a great deal in the summer. Locally it is explained as the reports of the guns of Indians shooting porpoises off the islands of Campobello and Grand Manan; but, for several reasons, I never believed this: in fact, I have always been sure it must be due to some other cause, though I could think of no explanation. It is heard most often in summer, in rather still and warm weather, on those days when the heat-haze hovers upon the ocean, and appears to come from seaward.

W. F. GANONG.

Smith College, Northampton, Mass., U.S.A.

THE "humming in the air," to which Mr. Tomlinson calls attention in your last number, is noticed in White's "Selborne." "There is a natural occurrence to be met with upon the

highest part of our downs in hot summer days, which always amuses me much, without giving me any satisfaction with respect to the cause of it; and that is a loud audible humming as of bees in the air, though not one insect is to be seen. This sound is to be heard distinctly the whole common through, from the Moneydells to my avenue gate." (Vol. ii. p. 94, Macmillan's edition.) W. TUCKNELL.

November 30.

Fireball of November 22.

ON November 22, at about 6h. 51m. I observed, in a sky quite overcast, a brilliant prolonged flash quite different to lightning. The whole firmament was illuminated for more than a second with an intensity greater than that which the full moon could have occasioned, and the glow seemed strongest in the south-east. Not a star was visible, but though the origin of the outburst could not be observed, no doubt existed that a fireball of the most brilliant type had fallen.

Mr. R. Sheward's letter from Eastbourne (NATURE, November 28, p. 78) affirms this conclusion, and it would be well if he or others who witnessed this striking object would give particulars as to the path it traversed. Appearing, as it did, at a convenient time in the evening, it must have had many observers, though unfortunately in the west of England the sky was veiled in cloud. For purposes of calculation it is not sufficient to have descriptions which merely indicate the general direction of the meteor's flight, as, for example, from east-north-east to west-south-west. We require to know the altitudes as well as the azimuths of the initial and terminal points, or the co-ordinates read from a celestial globe or star chart. A particular account of the path relatively to the stars near would be equally useful.

It is to be hoped that such information will be forthcoming in regard to this splendid meteor, which, from the manner in which it illuminated the clouded sky, must have been a very exceptional object of its class.

At this period in November many large fireballs are directed from the region of Taurus; but it is impossible to say, in the absence of necessary details, whether or not the fine meteor of November 22 last belonged to the Taurid stream.

Bristol, November 29. W. F. DENNING.

IN reference to the letter of Mr. Sheward in last week's NATURE, it may be of interest to mention that whilst talking to a friend in a dark road in this locality on the evening of November 22, the sky at the time being entirely overcast, we were startled by the sudden illumination of the clouds as if by the outburst of a bright light above them. The effect was similar to that which might have been produced by the explosion of a large magnesium shell sufficiently brilliant to illuminate the entire sky. The light appeared suddenly, but faded out gradually, its estimated duration being three seconds. It appeared to me to emanate from a point in the north-east, at an altitude of about 60°. My friend, whose face was turned in the opposite direction, could not localise the outburst, though he remarked that the light suffused the clouds almost equally in the west and south-west. I noted the time as 6 48 p.m., which so nearly coincides with that mentioned by Mr. Sheward, that although so far apart it seems probable that we were witnesses of the same phenomenon. R. T. LEWIS.

Ealing, W., December 2.

A Joint Meeting of Associations for the Advancement of Science.

MY suggestion for a joint meeting of the British, Australasian, and American Associations for the Advancement of Science at San Francisco in 1897, at some time conveniently near to that of the Toronto meeting of the British Association, published in your issue of October 24, meets favourable reception in the United States and Canada. I have recently received a letter from Sir Wm. C. Van Horne, President of the Canadian Pacific Railroad, and a member of the British Association, in which he says that he will instruct his superintendent to reopen negotiations with other transcontinental roads to secure favourable rates of transportation. Prof. Joseph Le Conte, who has for years given earnest effort to secure a meeting of the Association on the Pacific coast, writes from Berkeley, California: "I will certainly interest myself in your scheme . . . I am glad you are moving the affair so early, and thank you for drawing my attention to it."

The following is a copy of a letter just received from the Mayor of San Francisco:—

MY DEAR SIR,—

Your communication of October 9, 1895, was received and thereafter forwarded to the Board of Supervisors.

That body, on October 28, 1895, passed a resolution, and it is herein inserted in print.

"*Resolution No.* 13, 120 (*Third Series*).

"Resolved—That his Honour the Mayor be, and is hereby empowered and requested to invite the American and Australian Associations for the Advancement of Science to meet in this city in 1897; also, to invite the British Association of the same character to meet said Associations in this city as invited guests, and to that end to take such action as may be proper to arrange for their comfort and accommodation on that occasion.

"And the clerk is hereby directed to advertise this resolution as required by law.

"Board of Supervisors, San Francisco, October 28, 1895."

Pursuant thereto, an invitation is thereby sent to your Society—the American Association for the Advancement of Science.

It is my sincere hope that San Francisco may have the good and rare fortune to receive the visit of all three of these distinguished bodies.

The gathering of the world's chosen scientists is at once recognised as of high importance to our Municipality.

Its citizens will feel honoured in extending a generous welcome to men eminent in the cause of truth, and representing the three great branches of the Anglo-Saxon races.

Should this invitation be accepted, an early notification thereof is requested.

Invitations have been sent to the British and Australian Associations. (L. S.) ADOLPH SUTRO.

Application will be made to Congress at its session, which begins on the first week of December, for an appropriation to assist the American Association for the Advancement of Science towards defraying the necessary expenses of holding a meeting so distant from the homes of most of our members. It is, of course, impossible to foretell what Congress may be willing to do in the matter; but as it has never before been asked to subsidise the Association, we may hope that some appropriation may be secured. WM. H. HALE.

Brooklyn, November 18.

The Metric System of Weights and Measures.

THE adoption of the metric system in this country can be best effected by first familiarising the people with it for some years. I would suggest that the following would form a good beginning:—

(1) Its adoption by the Post Office. At present the weight of a foreign letter that will go at the minimum rate, must not exceed ½ oz. if posted in England, while 15 grammes are allowed on the continent, which is rather more. The 15 grammes limit should be adopted in England for foreign postage, and 30 grammes for inland postage. Parcels and newspapers should also be charged according to the metric system.

(2) The metric system should be employed by the Meteorological Society and Meteorological Office. At present our weather statistics cannot be compared directly with those published on the continent. The same course should be also followed by other sciences (*e.g.* geology, astronomy, &c.) that still use miles, yards, feet, &c.

(3) Government topographical and geological maps should all bear a scale of metres and kilometres.

There are, of course, many other ways in which the metric system could be brought before the public.

December 2. JOHN W. EVANS.

"Dendrexetastes capitoides."

DR. FORBES has been kind enough to send me for examination the typical specimen of *Dendrexetastes capitoides* of Eyton, now in the Derby Museum, Liverpool, to which he has called attention in a letter in NATURE of October 24 last (NATURE, vol. lii. p. 619). I have compared it with specimen *a* of *Dendrexetastes temmincki* in the British Museum, and do not hesitate for a moment to say that they are referable to the same species. Both are from Cayenne, and of the ordinary unmistakable "Cayenne make." But it is quite true that, as pointed out by Dr. Forbes, the cross-bands on the belly, which

are very visible in the British Museum specimen, are quite non-apparent in the Derby Museum specimen. These cross-bands are, in all probability, remnants of the immature plumage, the British Museum specimen being not quite adult. I was, therefore, wrong in using this character ("Cat. Bds.," xv. p. 140) to separate *Dendrexetastes temmincki* from *D. devillii*, which, however, are quite different species, easily distinguishable by other characters. But *D. capitoides* = *D. temmincki* in my decided opinion, as has been stated in the "Catalogue."

P. L. Sclater.

"The Zoological Record."

In reference to the note in Nature of November 21, about the *Zoological Record* for 1894, I must ask to be allowed to say that it is stated in the preface that Prof. Hickson could not undertake a record of Cœlenterata. Consequently there has been no failure of contract on his part. Prof. Hickson has been a valued contributor to the *Record* for several years, and his work was always ready at the time agreed on.

Cambridge, November 23. D. Sharp,
Editor of the *Zoological Record*.

THE LONDON UNIVERSITY.

Fortune so far has not been too kind towards the efforts made for adding teaching functions to the existing University of London. As already chronicled in Nature, the answer of the late Government to the request of the deputation to Lord Rosebery from institutions mentioned in the Report of Lord Cowper's Commission was the introduction of Lord Playfair's "University of London Act, 1895," enacting the appointment of a Statutory Commission to give effect to the recommendations of the Royal Commission. Before it had been read a second time, the Government went out of office and the Bill was dropped. From reports which have lately appeared in the press, it would seem that on June 13 a deputation from the members of Convocation hostile to the scheme waited on the Duke of Devonshire and Lord Salisbury, then in Opposition, and were led to believe that these statesmen were not unwilling to support an amending clause to Lord Playfair's Bill, which would entail the scheme, when arranged by the Statutory Commission, being submitted to Convocation for approval in the manner prescribed for a senatorial election, *i.e.* by voting-papers. And by July 1, Sir John Lubbock, in seeking re-election for the University, had pledged himself to oppose the Statutory Commission Bill unless such a clause were inserted, and comes into line with those against whom he voted in the Senate a year previously. Following this, came the Duke of Devonshire's reference on August 15 to the "strong opposition taken by a large and not unimportant section of Convocation" to the scheme of Lord Cowper's Commission, coupled with the announcement that legislation on the subject would not be undertaken in the short session then commencing.

Judged from such incidents, the outlook could not be regarded as reassuring, and with the return of Ministers to town, steps have been taken to bring to the notice of the Government the urgent necessity of dealing with the burning question of a Teaching University for London. On November 21 the delegates represented on the deputation to Lord Rosebery, met at the University of London, and unanimously passed the following resolution:—

"That the Government be requested to introduce, at an early date, a Bill, similar to Lord Playfair's London University Commission Bill, 1895, appointing a Statutory Commission to carry out the recommendations of Lord Cowper's Commission, but with an added clause giving [in accordance with precedent Acts of similar tenor[1]] to all Institutions or persons directly affected by any Statute or Ordinance proposed by the Statutory Commission, a right of appeal to the Privy Council for the disallowance or alteration thereof, previous to such Ordinance being laid before Parliament for confirmation."

The Duke of Devonshire, on Thursday last, received a deputation in support of this resolution, the delegates present representing not only the institutions named in the Report of Lord Cowper's Commission, but also the members of that and of the earlier (Lord Selborne's) Commission on a Teaching University for London, as well as members of the recent Bryce Commission on Secondary Education. The deputation was introduced by Lord Kelvin, and its views were enforced by Prof. Rücker on behalf of the Senate of the University of London: Dr. Allchin for the Royal College of Physicians, Mr. Heath for the Royal College of Surgeons, Sir George Young (University College), Principal Wace (King's College), Dr. Frederick Taylor (Medical Schools), Principal Whitehouse (Nonconformist Theological Colleges), Sir Henry Roscoe (Association for promoting a Professorial University for London), Prof. Silvanus Thompson (Annual Committee of Convocation), and Mr. Anstie (Committee of Graduates).

In the presence of so emphatic an expression of the unanimity not only as to the need for but also the method of the reorganisation of the present University existing among the many institutions and persons interested in the settlement of this grave question, a sympathetic reply might surely have been expected from the official head of the Education Department. This, however, was not to be the case. The Duke, after conceding the representative character of the deputation, made no further reference to the manifold interests represented by the delegates; no reference to the needs of higher education in London; no reference to the widespread recognition of the necessity for a Teaching University without which, in view of the conflicting nature of the interests concerned, little approach towards a united appeal for a Commission with executive and judicial powers for their settlement could have been gained. On the contrary, his reply dwelt on the difficulty of securing the present status of the external students under the scheme of Lord Cowper's Commission, while admitting that the scheme and deputation were at one in insisting that this should be maintained unimpaired; on his desire to obtain, if possible, an expression of opinion on the subject from the external students, and on the differences in opinion which had arisen in Convocation about the scheme. In Convocation the Duke of Devonshire recognised three sections—those who accept the scheme with such modifications as may be made by the Statutory Commission, those who are irreconcilable, since they express the view that if a Teaching University for London is needed it should be founded apart from the existing University, and those who are of opinion that it would not be enough for the amendments they desired introduced in the scheme to go merely as recommendations to the Commissioners when appointed, whence their claim for a veto on the scheme when arranged, to which we may add a fourth, viz. the large proportion, nearly one half of the members, who, so far, have not been beguiled by the foregoing three to express any opinion at all. And recognising only these three, he dwelt on the expediency of everything possible being done to conciliate the opposition, if only on the ground that it is extremely desirable that the Bill, if it comes before Parliament, should come before it in a shape which should excite as little opposition as possible.

It is not too much to say that, in tendering this advice, the Duke showed that he had not had time to balance the relative importance of the views laid before him by the deputation from some members of Convocation in the summer, and those which had been so strongly urged by the delegates whom he was addressing. Had it been otherwise, the disparity between the interests involved is

[1] Oxford and Cambridge Act, 1877, sec 46.
Scottish University Act, 1889, sec. 20 (*a*).

so evident that advice to treat, apparently on a footing of equality, with a section of Convocation would never have been given to the deputation before him—a section of Convocation, be it remembered, which has rejected the conciliatory overtures of the Annual Committee of Convocation,[1] and has made common cause with the irreconcilables in promoting opposition to the scheme.

The Duke's reply has at least made one point clear. We now know that between the institutions concerned with higher education in London, and the realisation of their wishes, there only stands the opposition of a section of the graduates of the present University. Thus no alternative is left but to deal with the question again from this point of view. It must not be forgotten that Convocation, in the manner prescribed by the charter, has twice declared in favour of the scheme of Lord Cowper's Commission. But even were the members of Convocation as unanimous in opposition to the scheme as they are divided in opinion as to what measure of support should be accorded it, is it right or just that the organisation of London's unrivalled facilities for higher education should be delayed at the instance of a body of graduates of a State institution? The precedents are all the other way, as in the case of the Queen's University for Ireland, where the hostile vote of its Convocation was set aside by Lord Beaconsfield's Government, and the University reorganised as the Royal University for Ireland. For what is the position? The University of London, according to the clearly implied opinion, both of Lord Selborne's and Lord Cowper's Commissions, and to the widely-expressed opinion of those outside the University most competent to judge on educational matters, does not perform the duties now required of it. Lord Cowper's Commission, in its Report laid down the lines on which the University may be reorganised, so that it can become a Teaching University for London without interference with its present work. The principles of the proposed reconstruction have been accepted by all concerned, as well as by outside opinion, with a degree of approval no less remarkable for its wide extent than for the contrast it affords with the reception accorded to all previous schemes. But this approval is wholly conditional on the reorganisation being effected by legislative authority as recommended in the Report, a requirement so displeasing to a section of Convocation that to secure its assent to this procedure nothing less is demanded than a right to veto the scheme when arranged by the Statutory Commission, should the "opinion of Convocation as a whole," ascertained by voting-papers, be unfavourable to it. Is it not a truly Gilbertian idea that the graduates of a State-created, State-maintained Examining Board should be put in a position to veto the action of the State itself? The War Office clerks might with about as much reason have insisted that the scheme for the reorganisation of the War Office should be submitted to a *plébiscite* of their body for approval before it appeared in the Orders in Council.

The misconception which gives the name of University to the examining body at Burlington Gardens extends, perhaps not unnaturally, to the Convocation of its graduates, and mischievous expressions such as the "opinion of Convocation as a whole" find a too ready currency. Convocation, if it means anything, means an assemblage for the discussion of matters affecting itself or the body it represents, and, save in the case of the election of members of the Senate, where no useful purpose would be served by the public discussion of the merits of the candidates, decisions arrived at in its meetings are the decisions of the Convocation of the University. Whatever the opinions of members absent from the meetings of the Convocation, they have as much weight, or as little as those of members of Parliament absent from a division, and as the result of the division on Mr. Brodrick's famous motion showed, it is the opinion of the members present, and not that of the House of Commons "as a whole," which determines the fate not only of measures but ministries.

The necessity for a Teaching University has now become a "London question" of the first importance, and is becoming recognised as such by the metropolitan press. Matters obviously cannot be allowed to remain in their present position, and in the fact that he has still to be convinced an incentive will no doubt be found by those in charge of this matter to see that the misconceptions under which the Lord President labours are as far as possible removed. That the true inwardness of the proposal to make Convocation the arbiter in this great question is gaining public recognition cannot be doubted when "the small group whose views are represented by Sir John Lubbock, Dr. Collins, and Dr. Napier" is plainly told by the *Morning Leader* that its attitude is that of Demetrius the silversmith, and by the *Star* that "no Statutory Commission could for a moment accept such a position" as that proposed for it under the postal veto scheme. The following paragraph from *The Times* is so much to the point that we gladly give it further publicity :—

"We are sorry to see that the Duke of Devonshire speaks almost with bated breath of the reference of the question to a Statutory Commission. It would be 'a somewhat strong proceeding,' he says, to interfere in this way with the rights conferred on the Convocation of the University of London by the charter now in force. We cannot help feeling that this is a rather strange objection in the mouth of a statesman who has taken a leading part in the Liberal legislation of the past quarter of a century. Was it not by Statutory Commissions that sweeping reforms were introduced in the educational system and even the proprietary rights of the Universities of Oxford and Cambridge and their constituent colleges? Does the Duke of Devonshire imagine that those reforms would ever have been carried through if it had been left to the Convocation of Oxford or to the Convocation of Cambridge to give or withhold its sanction? On what ground, rational or sentimental, is an immunity from the reforming hand of Parliament claimed for the University of London which was denied to the historic and national foundations of Oxford and Cambridge? Indeed, the Convocation of the University of London has itself accepted in general terms the principle of the plan embodied in the Report of the Cowper Commission ; but the Duke of Devonshire is probably right in refusing to take this as an absolutely final expression of opinion. The Duke, however, goes further than this. He appears to insist that some additional means should be devised for ascertaining the views of those whom he calls the 'external students.' If unanimity, or anything approaching to it, is to be sought for as the result of this inquiry before the reforms unanimously demanded by the friends of higher education in London are initiated, the establishment of a Teaching University here, for which educational reformers have been struggling for years, will be substantially relegated to the next generation. This is a lame and impotent conclusion from which we should have thought the practical and positive temper of the Duke of Devonshire would recoil. The Parliamentary difficulties in the way of passing a Bill that meets with any strenuous resistance need not be insisted upon. The present Government, supported by an immense majority, and including so many distinguished statesmen, will find it no hopeless task to overcome such difficulties, especially as the Opposition are committed by Lord Playfair's Bill

[1] *Vide* Report of the Annual Committee presented to Convocation at its meeting on January 22, 1895.

to this very settlement of the question. But the problem will never be solved if the party of resistance are encouraged by being told that the acquiescence of the country graduates is indispensable, and that a measure brought in by the strongest Administration of the century cannot be passed if a handful of malcontents oppose it."

With such expressions of opinion as these before us we cannot doubt but that London will yet be roused to a sense of what it will lose if advantage is not taken of the present golden opportunity.

HENRY SEEBOHM.

THE death of Henry Seebohm was announced in one of the "leading dailies" last week, as that of a member of an eminent firm of steel-manufacturers. Steel-manufacturer Seebohm was, no doubt, and his steel was good; but his name will be remembered as that of an acute and hard-working naturalist long after the quality of his steel is forgotten.

Henry Seebohm was one of a family of Quakers of Scandinavian origin, as the name shows, but settled for several generations in England. He was born in 1832, at Bradford in Yorkshire, and educated at the Quakers' school in York. His father, who was a practical man and thought everybody should begin at the beginning, started him in life as a grocer's shop-boy, in order that he might be taught to tie up paper-parcels properly. After many vicissitudes in business, Seebohm settled down as a maker of pot-steel at Rotherham, and in due time achieved a handsome competence. From his earliest days devoted to natural history and especially to ornithology, Seebohm spent all his leisure in the study of birds, and made short excursions into different parts of Europe in order to obtain personal acquaintance with some of the rarer species. It was not, however, until about twenty years ago that his business pursuits permitted him to devote much time to scientific work. In 1875, in company with his friend Mr. J. Harvie Brown, he made his first great excursion to the valley of the Lower Petchora in North-east Russia. Of the remarkable ornithological discoveries effected on this occasion an account was first published in *The Ibis* for 1876. But a complete and most attractive narrative of the whole journey was subsequently prepared by Seebohm, and issued in 1880 under the title of "Siberia in Europe." In 1877 a longer and more adventurous journey was carried out into the Far East. On this occasion Seebohm visited the valley of the Yenesay, and in 1882 published his "Siberia in Asia" as a pendant to his former volume.

After this Seebohm commenced to put together the facts that he had accumulated, and the conclusions that he had arrived at on his much-loved subject of British birds. The first volume of his "History of British Birds and their Eggs" was issued in 1882. In 1885 the subject was concluded by the issue of the third and fourth volumes. It may be truly said that no other book of the sort has been prepared on the base of such wide and varied experiences. Having acquired from a brother ornithologist a special collection of wading-birds, Seebohm next turned his attention to this branch of ornithology, which had also particular attractions for him in connection with the migrant habits of this order, and in 1888 issued a beautifully illustrated quarto work "On the Geographical Distribution of Plovers, Sandpipers, and Snipes," which was, in fact, a complete "Monograph" of the birds of the order Limicolæ. He also wrote two treatises on the "Classification of Birds," the last of which was only published in the present year.

Seebohm was a most liberal contributor to the bird-collections of the British Museum, and from time to time made many very handsome contributions to them. He would purchase and present without the slightest hesitation any specimens that came into the market, if he thought there would be a difficulty in their acquirement by the Museum. He gave to the Museum the whole of his unrivalled series of eggs, and had it arranged along with the rest of the collection of these objects under his own personal supervision. He was also the compiler of the fifth volume of the great catalogue of birds published by the Trustees, which was issued in 1881. This related principally to the thrushes—a group with which Seebohm was specially familiar. In fact, he has long had in preparation a complete monograph of this group of birds, with coloured illustrations of every species, but has unfortunately left it unfinished at his decease.

Seebohm was elected a Fellow of the Zoological Society and of the British Ornithologists' Union in 1873, and from that date onwards was a leading spirit in the conduct of both these Societies, and a constant contributor to their publications. He was never elected a Fellow of the Royal Society, though put up as a candidate, and very strongly supported. Unfortunately occult influences interfered with his attainment of this honour. Seebohm, though one of the kindest natures possible, was occasionally a severe critic, and gave offence to sensitive individuals by stating the truth too plainly. The loss of an only son some years ago was a sad blow to Henry Seebohm; but he recovered this shock to a great degree, and returned to his usual pursuits. His last and fatal illness was consequent, as he believed, on an attack of influenza, which took place last spring. He died on the 26th ult., at his residence in South Kensington, where he had got together a splendid ornithological library and an almost unrivalled collection of British birds, leaving a vacuum in the ranks of living naturalists which it will be very difficult to fill.

NOTES.

THE first meeting of the General Committee formed for the purpose of establishing a memorial to the late Prof. Huxley was held on Wednesday, November 27, when it was resolved—"That the memorial do take the form of a statue to be placed in the Museum of Natural History, and a medal in connection with the Royal College of Science; and that the surplus be devoted to the furtherance of biological science, in some manner to be hereafter determined by the Committee, dependent upon the amount collected."

IT will be remembered by our mathematical readers that a Committee, including the names of many eminent mathematicians in both hemispheres, was formed in 1893 to obtain funds for a memorial to the renowned master of geometry—Lobatchefsky. The report of the Committee on what has been done in the matter has just been issued. The total sum received up to May last was 9071 roubles (£1417), and when all expenses had been paid the amount available for the memorial was 8840 roubles (£1381). This sum enables the Committee to carry out the double intention of founding an international prize for geometrical works, especially for those belonging to non-Euclidean geometry, and also to erect a bust of Lobatchefsky. Six thousand roubles have been put by to found the prize, which will consist of 500 roubles (nearly £80), to be given every third year for the best geometrical works or memoirs. The memoirs may be written in Russian, French, German, English, Italian, or Latin, and must be sent to the Physico-Mathematical Society at Kazan, at least a year before the adjudication of the prize. The first prize will be awarded on October 22 (November 3, new style), 1897. The sum remaining over and

above that devoted to found the prize will go towards erecting two busts of Lobatchefsky—one outside the University of Kazan, and the other in the interior of the University Buildings. The former bust, with its pedestal, will cost three thousand roubles, of which two thousand will come from the Lobatchefsky fund, and one thousand from the Municipal Council of Kazan. In the case of the second bust, which will be placed in the meeting-room of the University, two hundred roubles will be given from the fund; and the remainder of the cost will be defrayed by the Professors. All memoirs referring to Lobatchefsky and his geometry, together with the printed papers and manuscripts of the great geometer himself, are to be arranged in a separate collection, and named the "Bibliotheca Lobatcheoskiana."

MR. JOHN D. ROCKEFELLER'S recent gift of an additional million dollars (£200,000) to his munificent donations to the University of Chicago, and his promise of a similar contribution of two million dollars, were noted at the beginning of last month. Our readers will be interested to read Mr. Rockefeller's letter to the Trustees of the University, printed in *Science* of November 15:—"October 30, 1895. To the Trustees of the University of Chicago, T. W. Godspeed, D.D., Secretary. Gentlemen: I will contribute to the University of Chicago \$1,000,000 for endowment, payable January 1, 1896, in cash, or at my option, in approved interest-bearing securities at their fair market value. I will contribute in addition, \$2,000,000 for endowment or otherwise, as I may designate, payable in cash, or, at my option, in approved interest-bearing securities at their fair market value, but only in amounts equal to the contributions of others, in cash or its equivalent not hitherto promised, as the same shall be received by the University. This pledge shall be void as to any portion of the sum herein promised, which shall prove not to be payable on the above terms, on or before January 1, 1900. Yours very truly (signed), JOHN D. ROCKEFELLER." These gifts, remarks our contemporary, make the entire amount of Mr. Rockefeller's donations to the University of Chicago about 7,600,000 dollars, probably the largest gift ever made by an individual for educational or public purposes."

A QUARTER of a million dollars (£50,000) was, we understand from *Science*, granted by the last U.S. Legislature to the Regents of the University of California for the erection of a suitable building for the departments situated in San Francisco, the Colleges of Law, Medicine, Dentistry, Pharmacy, and Veterinary Surgery. Mr. Adolph Sutro, Mayor of San Francisco, has given a tract of thirteen acres as a site for the building. On the adjoining thirteen acres Mr. Sutro proposes to erect a building for his magnificent library of about two hundred and fifty thousand volumes.

IT is announced that at the instance of the Bureau des Longitudes, the French Minister of Marine has provided ships, men, and instruments for some seven expeditions, which are to make accurate (and as far as possible simultaneous) observations in different parts of the globe. One of the chief defects of the present state of knowledge of this important branch of terrestrial physics arises from the fact that past observations have been made in various ways, under very various conditions, and that a great part of it depends upon the scarcely scientific records of ordinary seamen. The French expeditions are to observe strict uniformity in their method of observation, and cannot fail to enhance the value of the work which England and America have begun in this direction.

AT the recent annual meeting of the Royal Society of Edinburgh, the following officers and members of Council were elected for the ensuing session:—President: The Right Hon. Lord Kelvin, F.R.S. Vice-Presidents: Prof. Copeland, Prof. James Geikie, F.R.S., the Hon. Lord Maclaren, the Rev. Prof. Flint, Prof. J. G. McKendrick, F.R.S., and Prof. Chrystal. General Secretary: Prof. P. G. Tait. Secretaries to Ordinary Meetings: Prof. Crum Brown, F.R.S., and Dr. John Murray. Treasurer: Mr. Philip R. D. Maclagan. Curator of Library and Museum: Dr. Alexander Buchan. Councillors: Dr. Alexander Bruce, Prof. Frederick O. Bower, F.R.S., Mr. A. Beatson Bell, Sir Arthur Mitchell, K.C.B., Prof. T. R. Fraser, Mr. Robert Munro, Dr. M. D. Noel Paton, Mr. C. G. Knatt, Sir W. Turner, F.R.S., Sir Stair Agnew, K.C.B., James Burgess, and Dr. John S. Mackay.

AS one of the results of the late Medical Congress, the *Pharmaceutical Journal* states that the Government of India have decided to institute an inquiry into the subject of the desirability of a more extended use of indigenous drugs. The Committee to which the Indian Government has decided to refer the whole question consists of Dr. George Watt, C.I.E., Surgeon Lieut.-Colonel C. J. H. Warden; and Brigade-Surgeon Lieut.-Colonel George King, F.R.S., C.I.E., Surgeon Lieut.-Colonel J. F. P. McConnell, and Rai Bahadur Kanny Loll Dey, C.I.E. The points to which the Government of India has particularly invited the attention of the Committee, with a view to their careful consideration, are the practicability as well as the utility of (*a*) encouraging the systematic cultivation of medicinal plants indigenous to India; (*b*) encouraging the increased use in medical depôts of drugs of known therapeutic value; and (*c*) sanctioning the manufacture of stable preparations of certain drugs at the depôts. With regard to these points, the Government of India desires that the members of the Committee shall consider, and report their opinion, as to the action which would be best calculated to give the suggested encouragement. The Committee will further consider, from a practical point of view, the question of initiating, as a Government measure, experiments to test the reputed therapeutic value of indigenous drugs.

THE next session of Parliament will, the *British Medical Journal* remarks, have before it a scheme for providing a supply of sea water for London and certain places on the route. The intention is to take in the water from the sea opposite Lancing, in Sussex, where all the pumping machinery will be situated. It will be pumped thence to a large reservoir in an elevated position at Steyning, whence it will flow by gravitation to another reservoir at Epsom. From this reservoir it will be distributed over London, the parts to be first supplied being the West-end and central portions. It is stated that local authorities will be supplied with sea water for flushing sewers, watering streets, and other public uses, such as swimming baths, and that sea water baths will be supplied to hotels, hospitals, schools, &c. As to any relief to present sources of water supply by using sea water for public purposes, it should be mentioned that the quantity proposed to be provided is stated to be only 10,000,000 gallons per day, while the average daily supply of water to London amounted in 1893 to over 190,000,000 gallons. If the scheme is carried into effect, it will have an important bearing upon the health of London.

ON Friday last, the new Museum of Natural History which has been erected at Perth by the Perthshire Society of Natural Science, at a cost of about £4000, was formally declared open by Sir William Flower, in the presence of a large and representative gathering. Mr. Henry Coates, the President of the Society, occupied the chair, and, in introducing Sir William Flower, he remarked that the idea of forming a Museum had been kept before their Society from its commencement, twenty-eight years ago. The first attempt to form a collection dated from 1869. In 1877 the late Sir Thomas Moncreiffe brought

forward a comprehensive scheme, which ultimately resulted in the erection of the Moncreiffe Memorial Museum. The available space was rapidly filled up, and in 1885 Dr. Buchanan White suggested a scheme for the enlargement of the premises. The scheme was embarked upon in 1892, and by the generous support of friends, and in particular the donation of Sir Robert Pullar, it had now reached its present successful completion. Sir William Flower, in declaring the Museum open, said he thought that this epoch in the history of the institution might mark a distinct advance in the educational history of the country. The foundation of such societies as the Perthshire Natural Science Society in all the principal centres of population was a proof that they fulfilled a natural want in the human mind in its present stage of development. Of the general value of museums, using the word in its widest sense, as collections of works of art and of nature, in the intellectual advance of mankind, there could be no question. How could science be studied without ready access to the materials upon which knowledge is built up? In many branches of science, especially those commonly called natural history, the progress was mainly commensurate with the abundance and accessibility of such materials. All would recognise the gradual development of the conception that the museum of the future was to have for its complete ideal not only the simple preservation of the objects contained in it, but also their arrangement in such a manner as to provide for the instruction of those who visited it. The value of a museum would be tested not only by its contents, but by the treatment of those contents as a means of advancing knowledge. What a museum really depended upon for its success and usefulness was not its building, not its cases, not even its specimens, but its curator. They might as well build a church and expect it to perform the duties required of it without a minister, or a school without a schoolmaster, or a garden without a gardener, as to build a museum and not provide a competent staff to take care of it. Complimenting the directors on the objects they had sought after in the arrangement of their museum, which was to provide a good local collection of natural products, as well as the formation of a type collection, Sir William Flower said every specimen should have its definite purpose, and he quoted the saying of Dr. Brown Goode that an efficient museum might be described as a collection of instructive labels, each illustrated by a well-selected specimen. Advocating the appointment of a paid curator, he said the great principle of expending public money upon purposes of education, though a comparatively new one, was now conceded upon all sides. The cost of supporting a few really efficient museums would be a mere trifle compared with the hundreds of thousands spent upon far less efficient modes of educating and elevating the people. He commended to the consideration of those who controlled the pecuniary funds of the city the great benefits they might confer on education by assisting to guarantee the stability of the Institution, which noble voluntary efforts had brought into the condition which enabled him to declare it open.

THE Gesellschaft für Erdkunde of Berlin has elected Mr. Scott Keltie, Dr. H. R. Mill, and Mr. E. G. Ravenstein, Corresponding Members, as a recognition of their work at the late International Geographical Congress.

THE Paris Academy of Sciences have elected M. Lannelongue Member of the Section of Medicine and Surgery, in the place of the late Prof. Verneuil. M. Charles Monod has been elected to succeed Prof. Verneuil as a Member of the Paris Academy of Medicine.

DR. G. LAGERHEIM (Trömso) has been appointed Professor of Botany and Director of the Botanical Institute to the University of Stockholm.

THE second series of lectures arranged by the Sunday Lecture Society begins on Sunday afternoon, December 8, in St. George's Hall, Langham Place, at 4 p.m., with a lecture by Sir Benjamin Ward Richardson, F.R.S. Lectures will subsequently be given by Mr. J. Churton Collins, Prof. Arthur Smithells, Prof. Vivian Lewes, Prof. Percy Frankland, F.R.S., Dr. Karl Leutzner, and Dr. Andrew Wilson.

A CORRESPONDENT in the United States writes:—"At the elections this month several very important matters not of a political nature were decided. In the State of New York, the measure to expend $9,000,000 on the State canals was approved by a large majority. The Erie Canal will be made nine feet deep, and somewhat widened, and improved locks will be built. Similar improvements will be made on the Oswego and Champlain Canals. The work will be pushed on rapidly, and facilities provided for the use of electric-motive power, to be furnished by the Falls of Niagara."

IN June 1894, Dr. A. Donaldson Smith, a young American physician, left England for an expedition across Somaliland to Lake Rudolf. He was accompanied by Mr. Gillett, who was recalled to England a few months later, and by Mr. Dodson, who acted as collector and taxidermist. The attempt to march straight from Milmill to Lake Abbai was frustrated by the Abyssinians, and Dr. Smith returned to the Webi Shebeyli. He left there in February last in order to try to reach Lake Rudolf by another route, and as he was not heard of till he arrived at Lamir in November, some anxiety was felt as to his safety. He has, however, brilliantly carried out the whole of his plans, and achieved the march from the coast of Somaliland to that of British East Africa, which has been attempted repeatedly since it was first projected by Burton. Dr. Smith has explored the country to the north of Lakes Rudolf and Stephani and Abbai, connecting the route of Teleki with that of the Abyssinian travellers. He also reports (*Times*, 2nd inst.) a race of dwarfs in this region. These must be the Doko, first reported by Harris in 1844 from information supplied by a native of Shoa, and whose existence has been repeatedly reaffirmed. Lake Rudolf has only previously been reached by Teleki and Höhnet; at the time of their visit the lake was brackish, but it is now fresh. Dr. Smith has brought back large collections, including fish from Rudolf, Stephani, and Abbai. He does not seem to have seen the snow-clad Wosho, reported by Abbadie; Mount Wosho will probably therefore have to be wiped off the map. Dr. Smith is expected to read his paper at the Geographical Society in January, when important additions to our knowledge of this part of Africa may be expected.

FURTHER interesting additions to our knowledge of the African fish-fauna may be hoped from the collection of Miss Kingsley, who returned on Saturday, 30th ult., from a courageous journey on the West Coast. Miss Kingsley ascended the Ogowe River to the French station at Njole, and thence journeyed northward to the Rembwe, a tributary of the Gaboon. She visited the Crystal Mountains. Subsequently she ascended the Cameroons, and climbed the highest peak, the summit of which was first reached by Burton and Mann in 1862. Miss Kingsley's field of exploration is sufficiently well known to preclude important geographical results, but many valuable ethnographical observations have been made and zoological specimens collected.

A CURIOUS method of silvering mirrors has recently been patented by M. Hans Boas, of Kiel (says *Engineering*). It is based upon the fact that, when one of the heavy metals forms the cathode of a vacuum tube, containing a trace of hydrogen, the metal is volatilised by the current, and is deposited as a firmly adherent and highly polished layer on the walls of the tube. The mirror thus produced is said to be of much greater brilliancy than can be obtained by ordinary methods.

THE *Times of Ceylon* learns that it is in contemplation to introduce the electric light into the Sivan Hindu Temple at Kochicadde, on the main road to Mutwal, Ceylon. The premises of this Hindu place of worship are at present lighted by gas, and the trustees propose to substitute the electric light for gas; but whether they will introduce it into the interior of the building, is a matter which is now under their consideration. It is said that, if the Sivan Hindu Temple introduce the innovation, the trustees of equally wealthy temples are sure to follow the example set by their brethren.

IN reference to his letter on the "Jelly-fish of Lake Urumiah" (NATURE, 1892, p. 294), Mr. Sclater informs us that he has lately received a letter from Mr. F. F. Irving, of the English Mission at Urmi, in Persia, stating that Mr. Irving has lately visited the lake, and has found, as has been described by Mr. Curzon, numerous specimens of the supposed jelly-fish in its waters. Mr. Irving says that it resembles a tiny shrimp when swimming, but that as soon as it is brought out it succumbs into a sort of gelatine mass without shape. Measures are being taken to secure the transmission home of specimens of this interesting organism.

AN instance of concerted harmony and measured time-keeping on the part of certain insects, described by Dr. G. M. Gould, of North Carolina, in a recent number of *Science*, has drawn several letters from entomologists on the subject. Probably most people would hardly recognise music in the stridulous noise made by members of the group Crytophyllus, or "Katydids," and would express surprise at the suggestion that there is any rhythm or unison in the sound. Dr. Gould, however, states that there is no doubt whatever that katydids keep time in their stridulations. So soon as the sun has set in North Carolina an orchestra of katydids begins to tune up. After a few preliminary raspings, the members of the orchestra begin to make their noises together; another orchestra at once answers them, and so they go on swing-swong, one set answering the other the whole night long. Mr. A. P. Bostwick adds his testimony to that of Dr. Gould as to the antiphonal rhythm of two orchestras of katydids. He has remarked that the antiphony is often very regular for several minutes, sometimes stopping short, and again becoming broken into irregular individual stridulation at the end. The exact unison of movement can hardly be purely mechanical, for the katydids often start their noises all at once. A difference of pitch between the notes of two orchestras was suspected by Dr. Gould; but Mr. Scudder, who has given much attention to the sounds made by locustarians, thinks this may have been only apparent, and due to difference in distance from the observer.

THAT real images of objects are formed upon the human retina seems to be supported by a series of experiments carried out by Mr. W. Ingles Rogers, and described by him in the *Amateur Photographer* for November 22. Mr. Rogers took a shilling and looked at it intently in ordinary daylight for a full minute, with the idea of fixing the image of it distinctly upon the retina. He then drew a yellow screen over the window of the room in which he sat, so as to exclude all actinic light, and, placing a photographic plate in a certain position, fixed his eyes upon the centre of the plate, at the same time allowing nothing but the image of the shilling to occupy his mind. He remained looking at the plate for forty-three minutes, and afterwards developed it, with the result that an outline of the coin was clearly shown upon it. The "psychogram," as the resulting picture is called, was sufficient to show that better results might confidently be expected. Accordingly, Mr. Rogers continued his experiments, and, in order that there should be no doubt about the *bonâ-fide* nature of the result, he produced a psychogram in the presence of three trustworthy witnesses, whose testimonies as to the genuineness of the photographs accompany Mr. Rogers's communication. On this occasion a postage-stamp was used instead of the coin. The stamp was looked at in a strong light for one minute. It was then removed, a plate was put in its place, and the plate was looked at for twenty minutes. The resulting psychogram is reproduced in our contemporary, and although there is an absence of detail, sufficient is seen to prove beyond doubt that a picture of an object, impressed upon the retina, can send out vibrations which will result in the production of an image upon a sensitive plate. The result is of such great interest not only to photographers, but to students of physiological optics, that we hope the experiments will be continued.

AT a recent meeting of the Paris Academy of Sciences, M. Mascart presented an interesting note on the rainfall at Athens, by M. D. Eginitis, based on observations made at the Observatory during 1878-94. The average yearly rainfall for this period was 16 inches, and the number of wet days 97·8. This amount is not very small; the reputed dryness of Athens is due to three other causes: (1) the considerable variation in the annual fall; thus in 1883 it amounted to 33·3 inches, while in 1891 it was only 8·1 inches, or half the normal value. The dry and wet years follow with some regularity; a very wet period occurs generally about every seventh year. (2) The annual range of the rainfall, which presents great irregularity. The wettest month, November, has an average fall of 3·1 inches; and the dryest, July, only 0·3 inch. From June to July the rainfall is very insignificant; at times there is none for three months. (3) The intensity; the falls being heavy, but of short duration. It rarely rains for a whole day, generally speaking, after a few hours of rainy weather the sky becomes quite clear. From observations taken at 8 a.m., 2 and 9 p.m., it is found that the amount of rainfall during the day is double what it is during the night; the maximum occurs during the afternoon, owing to the greater frequency of thunderstorms at that time. The great variation in the yearly rainfall is said to be due to the different amount of humidity brought by the equatorial air-current, according to the course it has taken in arriving at Athens.

A VALUABLE catalogue (No. 155) of choice and rare books, including selections from the libraries of the late Dr. Reginald S. Poole, and Prof. de Lacouperie, has been compiled and issued by Mr. Bernard Quaritch, 15 Piccadilly.

AT the recent meeting of the National Academy of Sciences' held at Philadelphia, the following papers were presented:—"On the Palæozoic Reptilian Order of the Cotylosauria," by Prof. E. D. Cope; "On a New Variable of Peculiar Character," by Dr. S. C. Chandler (see "Our Astronomical Column," p. 109); "On a Bone Cave at Port Kennedy, Pa," by Prof. E. D. Cope; "On Borings through the Coral Reef in Florida,' by Prof. A. Agassiz; "On the Alkali Uranates," by Prof. Wolcott Gibbs; "The Olindiadæ" and "New Campanulurian Medusæ," by Prof. W. K. Brooks; "The Filar Anemometer" and "The Counter-twisted Curl Aneroid," by Prof. Carl Barus; "On the Broadening of Spectral Lines by Temperature and Pressure," by Prof. A. A. Michelson; "On the Asteroids," by Prof. A. Hall; and "The Early Segregation of Fresh-water Types," by Dr. Theo. Gill.

THE fourth volume of *Transactions* of the Rochdale Literary and Scientific Society, covering the period 1893–1895, has reached us. Included in it are papers on "The Birds in Piethorn Valley," by Mr. W. Watts; "The Rainfall in Rochdale and the Neighbourhood," by Mr. J. R. Ashworth; "The Cold Weather at Facit, during the Winter of 1894-95," with instructive diagrams, by Mr. T. S. Smithson; and Recent Discoveries in the Manufacture of Indigo," by

Mr. W. H. Pennington. The volume represents a large amount of industry and research on the part of associates of the Society, and it will give a stimulus to the study of science in Lancashire. Another volume just published by a provincial Society is the Annual Report and *Transactions* (vol. xxix.) of the Naturalists' Field Club and Archæological Society of North Staffordshire. This volume is, as a whole, more scientific in character than that of the Rochdale Society. Reports are given of the work of the various sections of the Society concerned with observations in different branches of science, and we notice, among the other contents, an address by Dr. W. Hind; a paper on glacial theories, past and present, and their application to Staffordshire, by Mr. C. E. De Rance, and one on the occurrence of marine fossils in the coal-measures of North Staffordshire, by Mr. John Ward. Both volumes are very creditable records of the work of provincial scientific Societies.

WE have on our table several new editions of books previously reviewed in NATURE. Among these volumes is a second edition of "Modern Microscopy" (Baillière, Tindall, and Cox), a handbook for beginners, comprising a section on the microscope, and instructions for its use, by Mr. M. I. Cross; and on the preparation and mounting of microscopic objects, by Mr. Martin J. Cole. We welcome a second edition of "A Manual of Physics" by Dr. W. Peddie, bearing the same publishers' names. The work is an admirable text-book, which students of physics would do well to obtain. Messrs. Longmans, Green, and Co. have published an eighth edition of Mr. John Thornton's "Elementary Physiography"; and Messrs. Blackie and Son, the ninth edition of "Earth-Knowledge," by Mr. W. Jerome Harrison and H. Rowland Wakefield; both these books being intended for students in the physiography classes of the Department of Science and Art. Messrs. Blackie have issued also a fourth revised and enlarged edition of "Elementary Inorganic Chemistry," by Prof. A. Humboldt Sexton.

THE additions to the Zoological Society's Gardens during the past week include a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, presented by Mr. Percy A. Gore; a White-headed Sea-Eagle (*Haliaetus leucocephalus*) from Newfoundland, presented by Mr. Leicester Curzon Howe; a Chough (*Pyrhocorax graculus*), British, presented by Mr. Gerald Strickland: two Blood-breasted Pigeons (*Phlogœnas cruentata*) from the Philippine Islands, presented by Captain Harvey; two Greater Sulphur-crested Cockatoos (*Cacatua galerita*), a Crimson-winged Parrakeet (*Aprosmictus erythropterus*) from Australia, presented by Mrs. Morgan; two Barbary Wild Sheep (*Ovis tragelaphus*, ♂ ♂) from North Africa, deposited; a Great Northern Diver (*Colymbus glacialis*), twelve Snow Buntings (*Plectrophanes nivalis*), four Dunlins (*Tringa alpina*), a Golden Plover *Charadrius pluvialis*), a Grey Plover (*Squatarola helvetica*), British, a Bahama Duck (*Dafila bahamensis*) from South America, four Green-winged Doves (*Chalcophaps indica*) from India, two Bearded Vultures (*Gypætus barbatus*), European, purchased.

OUR ASTRONOMICAL COLUMN.

POSITIONS OF THE NEW COMETS.—As we go to press, the following calculated positions for the two new comets have been received from Kiel. The places are for Berlin midnight.

Perrine's Comet.

Date.		R.A. h. m. s.		Decl. ° ′
Dec. 7	...	14 52 37	...	−13 37·2

Brooks's Comet.

Date.		R.A. h. m. s.		Decl. ° ′
Dec 8	...	8 11 2	...	+44 28·2
10	...	7 45 57	...	+51 36·7
12	...	7 16 42	...	+57 23·5

SWIFT'S COMET, 1895 II.—Another comet has put in a claim to be considered the long-lost comet of Lexell; and the claim is perhaps based on a better foundation than any of the other competitors can show. Le Verrier has supported the comets of Faye and De Vico; more recently Brooks' comet of 1889 found a supporter in Dr. Chandler, but the claim was routed by the calculations of Mr. Lane Poor. M. Schulhof looked favourably for a while on the merits of Finlay, but finally inclined to the belief that the two comets had a common origin rather than absolute identity. The new comet Swift has much to recommend it to the consideration of astronomers (*Astr. Nach.*, No. 3318). In the first place, Tisserand's criterion is fairly well satisfied; next, the closest approach to the orbit of Jupiter, in the case of both comets, falls very nearly in the same longitude; further, of the various orbits along which Le Verrier showed Lexell might move, after the heavy perturbations of 1779, one can be selected which agrees very closely with the orbit of Swift. Moreover, this particular selection of the various orbits suggested by Le Verrier is supported by Clausens's work on the same comet. Here is the comparison:—

		Selected orbit of Lexell.		Orbit of Swift (Schulhof).
Long. of perihelion	...	330°·0	...	338°·1
Long. of node ...	...	169°·9	...	170°·3
Inclination ...	...	6°·0	...	3°·0
Excentricity ...	...	0·6317	...	0·6515
Semi-axis major ...	..	4·224	...	3·724
"Tisserand's criterion" ...		0·480	...	0·493
Long. of approach to ♃ ...		184°	...	179°·5

It is a question if the agreement is not too good, for the comet of Swift made a close approach to Jupiter in 1886, and underwent heavy perturbations. M. Schulhof is at present considering these; but till their character and amount is known, it is premature to decide this vexed question of identity. It is possible the question will not be set at rest till 1931, for the returns previous to that date are not very favourable for observation, and the comet may pass unnoticed. But in any case observations in large telescopes should be prosecuted as long as possible, in order to determine the mean motion with accuracy, with the view of assisting the re-discovery.

A PECULIAR VARIABLE STAR.—A variable star recently discovered by Mr. Chandler presents some very remarkable features (*Astronomical Journal*, No. 358). In the singularly short period of 5h. 31·15m., the magnitude of the star varies between 8·9 and 9·7, so that three or four of the principal phases may be observed in a single night. The variations are distinctly not of the Algol type, but maxima and minima are equally and sharply marked. The light-curve is also unlike those of the other class of short-period variables, such as δ Cephei and η Aquilæ, inasmuch as the rise to maximum and fall to minimum take place in equal periods.

The newly-discovered variable is designated U Pegasi, and its position for 1900 is R.A. 23h. 52m. 53s., Decl. 15° 23′·9; the elements of the variability are as follows:—

		G.M.T. d. h. m.	
Minimum, 1894 Sept.	...	22 14 56·0	+5h. 31m. 9·0s. E.
Maximum	...	22 17 41·6	

The probable error of the period is believed to be only a moderate fraction of a second.

It appears that Dr. Chandler discovered the variability of the star more than a year ago, but erroneously inferred that it was of the Algol type with a period of 2·06 days. Mr. Yendell confirmed the variability, and concluded that the period was 0·69d., or one-third of that assigned by Dr. Chandler; but it was still supposed to be of the Algol type. A more recent discussion of the observations, however, has established that this period must again be divided by three, and that the light-curve has the character to which reference is made above.

SATURN'S RINGS.—Some remarkable observations of the rings of Saturn are reported by A. Mascari, of the Catania Observatory (*Ast. Nach.*, 3318). Observing from July 25 to August 6 of the present year, he noticed certain dark spots on the crape ring, as well as bright ones on the brighter rings. Perhaps the most curious feature of these spots is their apparent permanence of form; for this is not easy to explain if the idea that the rings are composed of separate particles be accepted, as in that case

adjacent parts of the rings would have different angular velocities. It was found, also, that the external boundary of the outer ring apparently joined the inner bright ring at a point on its northern edge, while the crape ring was almost twice as wide in the northern as in the southern part. This imperfect symmetry of the outer ring and crape ring with the inner bright ring, suggests that they do not all rotate in one plane. The different divisions of the ring would thus cast shadows upon each other, the amount of shadow depending upon the inclination.

The colour of the crape ring is described as bluish, and the shadow of the globe on the rings was curved, with the convexity towards the planet. Encke's division was very feeble and uncertain during the observations. It is pointed out that future observations of the spots may throw further light upon the rotation and constitution of the rings.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

LAST Saturday being St. Andrew's Day, the Anniversary Meeting of the Royal Society was held in their apartments at Burlington House. The auditors of the Treasurer's accounts having read their report, the Secretary read the list of Fellows elected and deceased since the last Anniversary.

The qualifications of the new Fellows were given in NATURE of May 9 (vol. 52, p. 31). Since the last Anniversary Meeting, the Society has lost nineteen Fellows and seven Foreign Members, viz. :—

Bisset Hawkins, December 7, 1894, aged 98.
Pafnutij Tchebitchef, December 8, 1894, aged 73.
Arthur Cayley, January 26, 1895, aged 73.
Sir James Cockle, January 27, 1895, aged 76.
Rev. Thomas Penyngton Kirkman, February, 1895, aged 88.
John Whitaker Hulke, February 19, 1895, aged 64.
Henry Austin Bruce, Lord Aberdare, February 25, 1895, aged 80.
Sir William Scovell Savory, March 4, 1895, aged 69.
Sir Henry Creswicke Rawlinson, March 5, 1895, aged 84.
Albert William Beetham, March 11, 1895, aged 95.
James Dwight Dana, April 15, 1895, aged 82.
Carl Ludwig, April 24, 1895, aged 78.
Roundell Palmer, Earl of Selborne, May 4, 1895, aged 83.
Henry John Carter, May 4, 1895, aged 82.
Sir George Buchanan, May 5, 1895, aged 64.
Franz Ernst Neumann, May 23, 1895, aged 97.
Valentine Ball, June 15, 1895, aged 52.
William Crawford Williamson, June 23, 1895, aged 78.
Right Hon. Thomas Henry Huxley, June 29, 1895, aged 70.
Henri Ernest Baillon, July 19, 1895, aged 67.
Charles Cardale Babington, July 22, 1895, aged 86.
Sir John Tomes, July 29, 1895, aged 80.
John Syer Bristowe, August 20, 1895, aged 68.
Sven Ludwig Lovén, September 3, 1895, aged 86.
Louis Pasteur, September 28, 1895, aged 73.
George Edward Dobson, November 26, 1895, aged 47.

Lord Kelvin, the President, then delivered the Anniversary Address as follows :—

In Cayley we have lost one of the makers of mathematics, a poet in the true sense of the word, who made real for the world the ideas which his ever fertile imagination created for himself. He was the Senior Wrangler of my freshman's year at Cambridge, and I well remember to this day the admiration and awe with which, before the end of my first term just fifty-four years ago, I had learned to regard his mathematical powers. When a little later I attained to the honour of knowing him personally, the awe was evaporated by the sunshine of his genial kindness; the admiration has remained unabated to this day, and his friendship has been one of the valued possessions of my life. While we mourn his departure from among us we know with gratitude that he has left an imperishable monument of his life's work in the grand edition of his mathematical writings which the University Press of Cambridge gives to the world. The interesting and genuinely appreciative obituary notice of Arthur Cayley, contributed by our colleague, Prof. Forsyth, to the *Proceedings* of the Royal Society for the present year, has been reprinted as a preface to the eighth volume of his "Collected Mathematical Papers," which was published last August, rather more than half of it having been passed through the press by the author with notes and references, and the remainder simply reprinted from the original publications. Matter for two more such volumes remains to be reprinted.

At the good old age of ninety-seven the veteran Franz Ernst Neumann has left us. He has been one of the most profound and fertile of all the workers in mathematical physics of the nineteenth century. I remember with gratitude the admirable and suggestive theorem[1] on electromagnetic induction which I learned in 1848, from a first paper on the subject which he had communicated to the Berlin Academy of Sciences, and which, translated into French, was published in the April number of that year of Liouville's *Journal des Mathématiques*. That first paper and others which followed it on the same subject, and his papers on the physical theory of light and on elasticity, are grand and permanently valuable contributions to science.

The death of Huxley, one of my predecessors in the Presidential chair of the Royal Society, takes from us a man who can ill be spared. During the fifty years since he sailed from England, as assistant-surgeon on board H.M.S. *Rattlesnake*, bound for a surveying expedition in the southern seas, he had been a resolute and untiring searcher after truth, and an enthusiastically devoted teacher of what he learned from others and what he discovered by his own work in biological science. His first contribution to science was a short note communicated, while he was still a student in the Charing Cross Hospital, to the *Medical Times and Gazette*, describing a structure in the root-sheath of hair, which has since borne the name of Huxley's layer. It was followed by papers on the blood corpuscles of the *Amphioxus lanceolatus* and on the anatomy and affinities of the family of *Medusæ*, for the British Association and the Royal Society; and several other articles on various biological subjects, all describing some of the work of the leisure left him by his medical duties during his four years' cruise on board the *Rattlesnake*, which were sent home by him to England, and published during his absence. It is to be hoped that the long series, thus so well begun, of papers describing skilful and laborious research by which knowledge was increased in every department of biology, will be given to the world in collected form as soon as possible. Even those purely scientific papers contain ample evidence that Huxley's mind did not rest with the mere recording of results discovered by observation and experiment: in them, and in the nine volumes of collected essays which he has left us, we find everywhere traces of acute and profound philosophic thought. When he introduced the word agnostic to describe his own feeling with reference to the origin and continuance of life, he confessed himself to be in the presence of mysteries on which science had not been strong enough to enlighten us; and he chose the word wisely and well. It is a word which, even though negative in character, may be helpful to all philosophers and theologians. If religion means strenuousness in doing right and trying to do right, who has earned the title of a religious man better than Huxley?

Another name literally of world-wide fame, Louis Pasteur, stands next to the end of our list of losses. Before he entered on his grand biological work, Pasteur made a discovery of first-rate importance in physics and chemistry—the formation of crystals, visibly right-handed and left-handed, from a solution of racemate of soda and ammonia; and the extraction of ordinary tartaric acid and of a kind of tartaric acid not previously known, from solutions obtained by picking out the crystals separately and redissolving: the new kind of tartaric acid having the property of producing the opposite rotatory effect on the plane of polarisation of light to that produced by ordinary tartaric acid From 1848 to 1857 he was chiefly occupied with researches related to the subject of that great discovery, as may be seen from the titles of the first twenty-two of his papers in the Royal Society Catalogue. His work of those nine years led up from Biot's fundamental discovery of the dioptric heliçoidal property of liquids and vapours, to the enrichment of chemistry by the annexation of a new province called stereochemistry, splendidly and fruitfully developed twenty years later by Le Bel and Van 't Hoff. Near the end of 1857 his twenty-third paper appeared, three pages, in the *Comptes rendus*, "Sur la Fermentation appelée lactique." It shows that he had then entered on the

[1] Quoted in "Mathematical and Physical Papers" (Sir William Thomson), p. 92, vol. i.

line of research to which he devoted the rest of his life, and by which he conferred untold benefits on humanity and the lower animals. As I had occasion to remark in my Presidential Address of last year, Helmholtz had in his earliest work proved almost to a certainty "that the actual presence of a living creature—vibrio, as he called it, bacterium as we more commonly call it now—is necessary for either fermentation or putrefaction." Pasteur gave complete demonstration of that conclusion, and early expanded it to vast and previously undreamt of extensions of its application. The first great practical application of his views was made by Lister about 1863-65, then my colleague in the University of Glasgow, now recommended by your Council as my successor to the Presidency of the Royal Society. From Pasteur's discoveries he was led to work out the principles of his antiseptic surgery, the practice of which he commenced in the Glasgow Royal Infirmary in the summer of 1865.

Having been led to trace microbes as the origin not only of fermentation and putrefaction, but of a vast array of destructive blights happening to plants and animals—vines, silkworms, birds, cattle, and mankind—Pasteur was forced to take up the question, as of supreme practical importance, "Whence came these microbes, and what are their antecedents?" From warmth and moisture, as we see by turning up a stone in a field, I was told forty years ago by an Arran farmer well versed in the popular literature of the day. We are sometimes told the same thing in scientific journals of 1895 under the more learned disguise perhaps of abiogenesis, or the fortuitous concourse of atoms, not tested by the calculus of probabilities. Without wasting words to prove theoretically that, while stones falling together may, as we all believe they have actually done, make a solar system with a habitable planet or planets, they cannot make a man, or a microbe, or an organic cell with its property of heredity, Pasteur set about practically to trace the antecedents of every microbe he met with, and he found for it in every case a living thing, whether in the air, or in water, or in earth. During nearly all the latter part of his life and to the end Pasteur devoted himself to biological research, and to vigorous practical realisation of its benefits for the world.

Turning now to the business of the Royal Society since our last Anniversary Meeting, I am glad to be able to report that excellent progress has been made with the "Catalogue of Scientific Papers." Vol. xi. of the Catalogue, under authors' names, completing the alphabet, is on the eve of issue, and the supplementary volume is far advanced.

The movement which led to the inception of the Catalogue dates back forty years—to the first meeting of the British Association in Glasgow, when Prof. Henry, of Washington, communicated a proposal for the publication of a catalogue of philosophical memoirs scattered throughout the Transactions of Societies in Europe and America, with the offer of co-operation on the part of the Smithsonian Institution.

The proposal was referred to a committee consisting of Mr. Cayley, Mr. Grant, and Mr. Gabriel Stokes. The year after, at the Cheltenham meeting, this committee propounded a scheme for a Catalogue, embracing the mathematical and physical sciences, to include both authors' names and subjects. Besides, Transactions and Proceedings of Societies, journals, ephemerides, volumes of observations, and other collections not coming under these heads were to be indexed.

This scheme came before the Royal Society in March 1857, in consequence of a request made by General Sabine at the instance of the British Association. Considerable discussion took place, and eventually it was decided to prepare a *manuscript* Catalogue of periodical works in the Royal Society's library, to include all the sciences, the question of printing being deferred; and to do the work at the Society's sole charge. Subsequently it was resolved to extend the Catalogue to works in other libraries not included in that of the Royal Society.

In 1864 it was decided to offer the Catalogue to Government for publication, and in 1866 the printing of the first series of the Catalogue, covering the period from 1800 to 1863, was commenced by the Stationery Office. The sixth and last volume of the series was published in 1872. Two additional volumes, covering the period 1863-1873, were published in 1879. The Treasury then declined to continue the publication of the Catalogue, which, however, was undertaken by the Society, assisted by a sum of £1000 voted by Parliament towards the charges of publication of the decade 1873-1883. The unexpended portion of this grant was invested in a policy, under which £1000 will become available for the purposes of the Catalogue in October, 1899.

So far back as June, 1864, it was resolved by the Council that the Catalogue according to authors should be followed by the immediate publication of an Index according to subjects. Such an Index Rerum was constantly under consideration, and many plans for its preparation have been discussed. The work at last took practical shape in 1893, when our Fellow Mr. Ludwig Mond most generously presented a sum of £2000 to the Society, in aid of the work of preparing the Catalogue and the Subject Index. Out of this liberal donation there remains unexpended a sum of £1500. A special staff was organised, by whom more than 140,000 slips have now been mounted and arranged in boxes, and of these over 46,000 have already been provisionally prepared for press. Since the last Anniversary, the department has to some extent been reorganised by the Committee, women being now employed in the Index Rerum Department, and Miss Chambers having been entrusted with full control over the whole. The total number of women employed in the two departments including junior copyists is now twelve.

It has, however, long been felt that the continuation of such a work was almost beyond the resources of the Royal Society, and therefore about two years ago a committee was appointed to take into consideration a suggestion that the preparation of complete indexes to scientific publications should be effected by international co-operation.

This very important subject has continued to engage the attention of the Council during the past year; and the suggestion of international co-operation having been recommended to Her Majesty's Government for favourable consideration, official invitations have been issued to an International Conference to be held in London in July next.

Meanwhile others have been equally aware of the great importance attaching to the indexing of literature, and only in September last an International Institute of Bibliography was established by Royal Decree in Brussels.

Two gentlemen in that city, MM. Otlet and La Fontaine, have, during the past half-dozen years, devoted themselves to the study of modern methods of bibliographic classification, specially with reference to sociology, and their work has been supported by the Belgian Government. They were led to adopt the decimal system devised by Melvil Dewey, which is popular with American librarians, and having made a careful study of its application, have become so impressed with its value that they have developed an extraordinarily comprehensive scheme applicable to literature generally.

An invitation to attend a conference in Brussels at the beginning of September last was received by the Royal Society early in August, too late unfortunately to permit of a representative being present.

At the conference held there on September 2 to 4, a number of resolutions to establish an International Institute of Bibliography as a development of the work begun by the above-mentioned gentlemen, were arrived at, and by a Royal Decree of September 12, 1895, such an office was established.

Your senior Secretary had an opportunity, when in Brussels recently, of visiting the office which has been established, and of seeing the skill and zeal with which the preliminary preparations have been made to carry the work into execution.

All must admire the energy and enterprise which has thus been displayed in Belgium. At the same time, the magnitude of the work and the importance of the interests involved are such that it appears most desirable that the action which the Royal Society has already taken for an International Conference should be persevered in, so that decisions may be arrived at which may ensure, if possible, complete success. The enterprise is one in which we, in consequence of our long connection with such work, are most deeply interested; it is also one which may well become of exceeding value to science generally. But it is impossible to overrate the difficulties connected with it; and to avoid unnecessary complications in the future it is essential that very many questions—especially the division of the subject matter in the various branches of science and the nomenclature to be used—be taken into consideration by competent bodies and settled by general agreement.

In my last Anniversary Address I mentioned that the Library Committee, in view of the great accumulation of the stock of *Philosophical Transactions*, were taking measures to make the memoirs composing the volumes separately available to the public, which, while facilitating the sale, would increase their

utility. I have now the pleasure to announce that arrangements have been made with Messrs. Dulau and Co. to carry out this suggestion, and that Messrs. Dulau have, at their own expense, issued a very useful alphabetical list of all the papers in the *Philosophical Transactions*, from the year 1800 to the present time, any of which may now be separately purchased by the public.

The great and increasing success of our annual soirées has led the House and Soirée Committee to recommend to the Council that in addition to the two conversaziones held in May and June, some informal receptions for the Fellows should also be occasionally held. This suggestion was readily adopted by the Council, and the first of these receptions was held last month.

The Water Research Committee have continued the labours which they commenced in conjunction with the London County Council four years ago, and although the County Council no longer contributes to the expenses, the Committee have been able to carry on the researches, partly by means of an assignment from the Government grant, and partly by a grant from the fund established in 1891, by his Excellency Dr. Gunning. A Report, of 200 pages, by Prof. Marshall Ward, forming the Fourth Report to the Committee, was presented to the Council of the Royal Society last March, and has been published in the *Proceedings*. This Report treats on the biology of *Bacillus ramosus* (Fraenkel), a schizomycete of the River Thames.

With respect to the Gunning Fund which I have just now mentioned, the Committee appointed by the Council to consider and report upon the best terms for carrying out the trust, made the following recommendations, which, with Dr. Gunning's approval, were adopted by the Council:—

"(1) That the Fund should not be applied in the form of a prize, medal, or reward, but should be devoted to the furtherance of knowledge in some special direction.

"(2) That, by preference, the interest accruing from the Fund during every three years be applied for the promotion of Physical Science and of Biology alternately.

"(3) That aid should, by preference, thus be given in Physical Science and Biology respectively, either to investigations or operations which require to be repeated from time to time, or to the development of some specified continued line of research."

The Council, while adhering to the policy of retrenchment touched upon in my last address, have had to recognise the fact that the Society was, at that time, already committed to a large amount of publication, a great bulk of printed matter being almost ready for issue. This accumulation has been rapidly worked off during the past session, with the result that the Council, notwithstanding that every effort has been made to limit the amount of fresh publication, have issued in the mathematical and physical section of the *Philosophical Transactions* no less than thirty-one papers, and in the biological section twenty-one. The two sections together contain in all 2259 pages of letterpress and sixty-one plates. Of the *Proceedings*, fourteen numbers have been issued, containing 1356 pages.

While determined not to depart from the policy of avoiding all unnecessary expenditure on publication, the Council felt that with only the funds hitherto at its disposal it could not effect the requisite diminution of expenditure without diminishing the efficiency of the Royal Society in promoting the augmentation of natural knowledge, which is the reason for its existence. An application to the Treasury for additional funds was therefore made by a resolution of Council adopted at its meeting of June 20 last. I am happy to say that a favourable answer has been received, and a grant of £1000 a year has been given by the Treasury to the Royal Society on the purpose of aiding in the adequate publication of scientific matter, whether in the *Transactions* or *Proceedings* of the Society or through other channels and in other ways.

At a meeting of the Council on October 17 it was resolved to send to the Institute of France the following address on the occasion of the centenary of its foundation; and it was agreed to authorise the President and Treasurer to represent the Royal Society at the commemoration to be held in Paris from October 23 to 26:—

"The President and Council of the Royal Society of London offer to the Institut de France their most cordial congratulations on the auspicious occasion of the centenary of its existence, which it is now about to celebrate.

"The President and Council are well aware that various ancient Academies flourished in France long before the official foundation of the Institùt as a means of recording discoveries and promoting arts and sciences, and that much of that great advance in human knowledge which took place during the 17th and 18th centuries was due to the labours of members of the French Academy of Science.

"The foundation of the Institut, however, comprising as it does five Academies, each with its own special sphere of action, but all united as one harmonious whole, constantly investigating the laws of nature and the developments of art, constitutes an era in the history of civilisation.

"It would be an endless task to attempt to enumerate the branches of human knowledge which during the past century have benefited by the labours of the Institut. It is a body of which not only France but the whole of the civilised world may be justly proud.

"It is sad to think, that just at the moment of a commemoration which would otherwise have been celebrated with unalloyed pleasure, Science has to mourn the loss of one of her most distinguished votaries. The single-minded and devoted labours of Pasteur, and their beneficial results to man and the domestic animals, are recognised throughout the whole world with the highest gratitude and admiration. The Royal Society assures the members of the Institut of its hearty sympathy in the sad loss that they and humanity at large have sustained.

"That the Institut may long continue to exist and prosper, and that each succeeding century may witness an ample harvest from its labours, is the heartfelt wish of the President and Council of the Royal Society.

(Signed) "KELVIN,
"*Pres. R.S.*"

I had the honour of presenting this address to the President of the Institute of France in person. For myself and other Fellows of the Royal Society who were present along with me I may be allowed to say that we were much gratified with the friendly and fraternal reception accorded to us, as colleagues and fellow labourers in the work of the Institute.

I am sorry to say that we are now losing the service, as Assistant-Secretary, of Mr. Herbert Rix, who, after seventeen years of faithful work for the Royal Society, retires from this post, as he finds the necessarily increased anxiety and burden of the office to be too great a strain upon his health. We all feel grateful to him for the manner in which he has discharged his duties from the time he first entered the service of the Royal Society; and I am sure the Fellows generally will agree with the Council in being pleased that we have been able to arrange to still have Mr. Rix to help us in our work, in the less arduous post of Secretary to the Government Grant Committee.

A very important scientific event of the past year, resulting from work initiated by the Royal Society a quarter of a century ago, is the completion of the "Report of the *Challenger* Expedition," in fifty large royal quarto volumes containing 29,500 pages, and illustrated by over 3000 lithographic plates, copper-plates, charts, maps, and diagrams. I may remind you that H.M.S. *Challenger* was fitted out by the Government in 1872, on the recommendation of the Royal Society, and was absent for nearly four years on an exploration of the Great Ocean Basins. The publication of the numerous observations, which have enriched almost every branch of science, was at first carried on under the direction of Sir C. Wyville Thomson, and subsequently by Mr. John Murray.

I have been myself much struck with the extreme beauty of many of the plates contained in these volumes; and, though no expert in the subject, I may be allowed to say that I believe nothing more admirable has been hitherto given to the world in the way of illustration and representation of biological subjects. Of the maps, I may confidently say that they are models of careful, accurate, and elaborate work. Two volumes of the Report deal with the narrative of the voyage, three volumes with the physics and chemistry of the ocean, one volume with deap-sea deposits and geology, two volumes with botany, forty volumes with marine zoology, and two volumes are devoted to a summary of the scientific results.

How highly the work of the *Challenger* expedition is appreciated by those best qualified to judge of the merits of its results is illustrated by the following words, spoken by Milne-Edwards at a meeting of the International Congress of Zoology, held last September in Leiden:—L'expédition du *Challenger* a porté des fruits merveilleux. Ceux qui l'ont organisé, ceux qui y ont pris part, et dont quelques-uns ne sont plus ici pour

recueillir le prix de leurs efforts, ceux qui en ont étudié les résultats, ont rendu des services dont nous leur sommes profondément reconnaissants. Le monument scientifique ainsi élevé par les savants anglais constitue un titre de gloire dont une nation a le droit d'être fière."

The contributors to this gigantic Report are, for the most part, natives of the United Kingdom and the British Colonies, but the scientific men of nearly every civilised State are represented among the authors. The British and foreign contributors are seventy-six in number, and many scientific men whose names do not appear on the title-pages of the special memoirs have taken part in the physical and chemical researches performed in connection with the work of the expedition. Among the contributors we find the names of Alexander Agassiz, Ernst Haeckel, P. G. Tait, G. O. Sars, F. E. Schulze, T. H. Huxley, Rudolph Bergh, A. v. Kölliker, A. Renard, W. K. Brooks, N. N. Polejeff, Th. Studer, A. A. W. Hubrecht, W. Dittmar, Sir William Turner, A. Günther. Before the end of the present meeting I shall have the pleasure of presenting to Mr. Murray one of the Royal medals, which has been awarded to him by the Council of the Royal Society, to mark their appreciation of his editorship of this great work, and of his own scientific contributions to it.

In my Presidential Address of last year I took occasion to refer to Lord Rayleigh's discovery that the gas which remains when oxygen, vapour of water, and carbonic acid are removed from common air, is denser than nitrogen extracted from chemical compounds; and I was then able to tell you of the consequent discovery that our atmosphere contains a fifth constituent which is denser than nitrogen. This discovery had been thoroughly established by Rayleigh, in association with Ramsay, who had joined him in the work; but no details had then been published. They had succeeded in isolating the new constituent by extracting all the four previously known constituents (oxygen, nitrogen, aqueous vapour, carbonic acid) from air, and they were energetically at work with a view to discovering its properties. I concluded my last year's Address by expressing the hope that their work would give us, "before the next Anniversary Meeting of the Royal Society, much knowledge of the properties, both physical and chemical, of the hitherto unknown and still anonymous fifth constituent of our atmosphere." That hope, as you all know, has been splendidly fulfilled. They early discovered a name for it, Argon, because exhaustive chemical investigation gave them no evidence of its chemical combination with any other known element. They found its density to be very high, 20 (that of oxygen being called 16), and the ratio of its specific heats $1\frac{2}{3}$. Olzewski, experimenting on a specimen sent to him by Ramsay, succeeded in liquefying it, and found its critical pressure to be 50·6 atmospheres, and its critical temperature $-121°$. These results were communicated in a joint paper by Rayleigh and Ramsay to the Royal Society at a memorable meeting, held in the theatre of the University of London, because our ordinary meeting-room was not large enough to contain all who wished to hear it. It will be gratifying to Fellows of the Royal Society to know that the Smithsonian Institution of Washington gave to Lord Rayleigh and Prof. William Ramsay the first Hodgkins' prize for their "Memoir on Argon: a New Constituent of the Atmosphere." This memoir had been communicated to Washington before the end of December 1894.

Since the dates of those first communications much work has been done by various observers on the spectrum analysis of argon. In a communication by Rayleigh to the recent meeting of the British Association, we find a very accurate determination of its refractive index and its viscosity. Ramsay, in trying for clues to compounds of argon, had his attention called by Mr. Miers (of the British Museum) to a paper by Hillebrande, telling that cleveite (a rare Norwegian mineral which consists chiefly of uranate of lead) gives out 2 per cent. of gas, supposed to be nitrogen, when warmed with weak sulphuric acid. Ramsay, thinking the so-called nitrogen might turn out to be argon, experimented on the mineral. He found that the gas evolved, by heating it in sulphuric acid, contained a trace of nitrogen, which he removed by the Cavendish process of sparking with oxygen in presence of alkaline liquor. The residue was proved by the spectrum test to contain argon, but to contain also another gas, not argon, showing itself by a brilliant yellow line. This line was identified by Crookes as the "helium line," discovered thirty years ago by Lockyer, who, finding it to have been not discovered in the spectrum of any terrestrial substance spectroscopically examined up to that time, attributed it to a substance in the sun's atmosphere, which he called helium. Thus, a substance, discovered thirty years ago in the sun's atmosphere, and accordingly named from the sun, has been found in a terrestrial mineral by Ramsay, in his quest after argon. Having got helium into his laboratory, he found its density to be less than 3·9 (ultimately reduced to 2), and, therefore, less than one-fifth (about one-tenth) of that of argon. He sent a specimen to Olzewski, who found (NATURE, October 3, 1895) that the treatment by which he had succeeded in liquefying hydrogen—namely, compressing with a pressure of 140 atmospheres, cooling to the temperature of liquid air boiling at low pressure, and then expanding suddenly, showed no signs of liquefying helium.

Considering the uncertainty as to the density of the gas in which helium was identified, and the multiplicity of spectrums found for it by various experimenters, Lockyer, who experimented on some eighty minerals, and found the yellow line of helium in sixteen of them, thinks it most probable that it is not a single gas that is extracted either from cleveite or the other minerals, but a mixture of gases of which helium is one; and this view was supported by Runge and Paschen in their admirable spectroscopic analysis of argon and helium, communicated to the British Association ("British Association Report," Section A, September 18, 1895) at its recent meeting at Ipswich. It seems too early to feel sure that the helium found by Ramsay in the gas from cleveite, if perfectly purified of nitrogen and other known gases, is a single gas, or is a mixture or combination of several. Before another Anniversary Meeting of the Royal Society, it is probable that we shall have certain knowledge, without any doubt, as to this question. Meantime, at our present Anniversary, we may be satisfied to feel that if there are several new gases, of which one, at least, has density less than a quarter of that of oxygen, the discovery will be several times as interesting as if the helium now discovered proves to be only one gas.

COPLEY MEDAL.

Dr. Karl Weierstrass, For. Mem. R.S.

Dr. Karl Weierstrass is distinguished for his investigations in pure mathematics, extending over a period of fifty years. He is one of the great pure mathematicians of the century.

Among his researches, dealing with many branches of the science in which his work is of significant effect, may be specially mentioned :—

(i.) His investigations in pure algebra, particularly in relation to functions of real variables, to the considerations of convergence and divergence of series and products, and to the theory of bilinear and quadratic forms.

(ii.) His contributions to the general theory of functions of complex variables. This subject he has developed from its foundations, and has re-established it on a new basis, so that much of it is his creation. The extensions which he has made to this theory have of themselves proved sufficient to secure for him the distinction of an acknowledged master.

(iii.) His work in the theory of periodic functions. In particular, the advances made by him in the theory of Abelian transcendents, mark the chief algebraical development since the time of Abel and Jacobi, and they have stimulated others to further developments. Also the valuable advances made by him in the theory of elliptic functions have been fruitful and suggestive as the starting-points for researches by a number of distinguished mathematicians.

(iv.) His work in the calculus of variations, the best known published part of which relates to the theory of minimal surfaces.

Not least remarkable among his claims to originality is the method of proof which he has introduced in his investigations; he has associated a vigour and a strictness with the minutest details of his proofs that have not merely led to the sound establishment of propositions, but have indicated limitations and have suggested new ideas.

ROYAL MEDAL.

Dr. John Murray.

To Dr. John Murray one of the Royal Medals is awarded for his energetic and successful editorship of the Report of the *Challenger* Expedition, and for his own large contributions to the work of the expedition and to the scientific papers embodied in the Report. In this matter Dr. Murray's labours are recognised universally as having been of extreme value to zoological science. His own contributions to the elucidation of the material brought home by the *Challenger* have been of great

importance and originality. His researches on the deep sea deposits, and his general discussion of the oceanographic results of the expedition, are recognised as being of first-rate quality.

Dr. John Murray has already received the "Prix Cuvier" of the French Académie des Sciences, and it is right that the corresponding body in this country should take the first opportunity available to it, after the completion of the *Challenger* Reports, to express its appreciation of their value.

ROYAL MEDAL.

Prof. James Alfred Ewing, F.R.S.

A Royal Medal is conferred on Prof. J. A. Ewing for his investigations on magnetic induction in iron and other metals.

The magnetic properties of iron and steel when subjected to magnetising forces of different intensities, under various conditions of temperature and mechanical stress, have been studied by many physicists both in this country and abroad. In a series of papers which have appeared at intervals during the last fourteen years, Prof. Ewing has put on record a remarkable collection of experimental facts connected with these complicated subjects. In some of his results and methods he was anticipated by others, but apart from the wide extent of his investigations, he has displayed great sagacity and originality both in his more fundamental researches, and in the directions in which he has developed his work.

Having studied the behaviour of iron when subject to magnetic forces which vary in a cycle, he applied the same process to nickel, proving that, as in the case of iron, the susceptibility is constant for small forces, but that the range of force over which this law holds good is much larger for nickel than for iron.

Prof. Ewing has also investigated the behaviour of iron and steel of various qualities, of manganese steel, of cobalt and nickel, when placed in very strong magnetic fields, the intensity of which was raised to the splendid magnitude of 46,000 C.G.S. units in the air around the metal bar under observation. He thus showed experimentally, in corroboration and extension of Joule's primary discovery, that the intensity of magnetisation approaches asymptotically towards a limiting value, which it very nearly reaches before the magnetising force attains a comparatively small magnitude, and at which it remains constant while the magnetising force is increased without limit.

Not content with investigations such as these, Prof. Ewing has made an important advance in our knowledge of the probable constitution of magnetic substances. He constructed a model of such bodies by placing a number of small magnets near to each other so that each is free to rotate in a horizontal plane. These magnets, when disturbed, settled down into groups of more or less stable equilibrium, which are gradually broken up under the influence of increasing magnetic forces. This model suggests the novel and most important conclusion that the act of magnetisation is accompanied by the re-arrangement of similar groups of magnetic molecules. So closely does it reproduce the behaviour of iron, that it is possible not only to imitate the more prominent phenomena, to copy the curve of magnetisation, and the loops produced by cyclic forces, but also to detect minor details which were for long overlooked in iron itself.

Throughout these theoretical researches Prof. Ewing has paid attention to their practical applications. The well-known phenomenon which he has named "hysteresis" plays an important part in the action of transformers. He has, on this account, invented two instruments by which the magnetic properties of samples of iron can be readily tested.

Prof. Ewing's researches on magnetic induction are described in a series of memoirs published in the *Transactions* of the Royal Society, and in a number of shorter papers which appeared chiefly in the *Roy. Soc. Proc.* and the "Reports of the British Association." He ranks as one of the principal authorities on a subject of great theoretical and practical importance. He has thrown light upon the theory, and has facilitated its application to industry.

DAVY MEDAL.

Prof. William Ramsay, F.R.S.

Prof. Ramsay's earlier researches were in the department of organic chemistry. Nearly twenty years ago he was carrying on researches on picoline and its derivatives, which were published in the *Phil. Mag.* for 1887 and 1888, and on quinine and its decomposition products, the results of which were published in the *Chem. Soc. Trans.* for 1878 and 1879.

Prof. Ramsay's later researches have been more devoted to subjects in the borderland dividing chemistry and physics. In 1879 and 1881, he published in the *Chem. Soc. Trans.* four papers on molecular volumes, and between the years 1880 and 1892 he communicated to the Royal Society eight papers on the critical state and properties of liquids, two being published in the *Proceedings*, and six in the *Phil. Trans.* In 1893 he published the results of researches on molecular surface energy in the *Phil. Mag.*, the *Chem. Soc. Trans.*, and the *Proc. Roy. Soc.* In 1893 he communicated to the *Phil. Mag.* a very important paper on the expansion of rarefied gases.

But the researches on which the award of the Davy Medal to Prof. Ramsay is chiefly founded are, firstly, those which he has carried on, in conjunction with Lord Rayleigh, in the investigation of the properties of argon, and in the discovery of improved and rapid methods of getting it from the atmosphere; and, secondly, his discovery in certain rare minerals of a new elementary gas which appears to be identical with the hitherto hypothetical solar element, to which Mr. Lockyer many years ago gave the name of "helium." The spectrum of this terrestrial gas was seen at first as an extremely narrow and sharp line of a brilliant yellow colour, close to, and slightly more refrangible than, the sodium lines D_1 and D_2, and having a wave-length near to 5876, this, according to recent determinations, being the wave-length of the solar line of helium, or, as it is usually designated, D_3. Shortly after its discovery, Prof. Runge, of Hanover, announced that the yellow line of Ramsay's gas was double, consisting of a strong component having a wave-length of 5875·88, and a faint component having a wave-length of 5876·21. As no observer had seen the solar line, D_3, double doubt was thrown on the first assumption that Prof. Ramsay had actually isolated a solar element hitherto unknown on the earth. Within the last few weeks, however, Dr. Huggins, in England, and Prof. Hale, in America, have detected the presence of a faint luminous companion of D_3 in the spectrum of the chromosphere, and as these solar lines have the same wave-lengths as those of the corresponding terrestrial lines, the doubts at first raised have been set at rest. The body giving rise to the solar line D_3, and Prof. Ramsay's new gas from cleveite, uraninite, bröggerite, monazite, and many other rare minerals, is now admitted by chemists, physicists, and astronomers to be the same substance—helium.

The conferring of the Davy Medal on Prof. Ramsay is a crowning act of recognition of his work on argon and helium, which has already been recognised as worthy of honour by scientific societies in other countries. For his discoveries on these gases he has already been awarded the Foreign Membership of the Société Philosophique de Genève, and of the Leyden Philosophical Society. He has had the Barnard Medal of the Columbia College awarded to him by the American Academy of Sciences, and within the last few weeks he has been elected a Foreign Correspondent of the French Académie des Sciences.

Five years have now passed since you elected me to be your President. Living at a distance of 400 miles from London, I felt that it could not be possible for me to accept the honour when the possibility of its being offered to me was first suggested. I accepted, with much misgiving as to my ability to perform the duty which would fall upon me; and now, after having been re-elected four times, I feel that if the interests of the Society have not suffered under my Presidency, it is chiefly because they have been so faithfully and unintermittently cared for and worked for by the other officers, the Treasurer and the Secretaries, who have left nothing undone that could be done to promote the welfare of the Royal Society. For their unfailing kindness to myself I can only offer my heartfelt thanks. I soon found that what I looked forward to with apprehension—the Council meetings, and as many of the ordinary meetings as I could attend, during my University session in Glasgow—were the reverse of fatiguing; and I am only sorry that I have been so many times obliged to forego the pleasure of performing that part of my Presidential duty. I look back otherwise with unmixed pleasure to all the meetings at which I have presided, and my sole regret now is—I cannot disguise it, and it is a very keen regret—that these five years are passed, and that to-day I cease to be your President. I thank you all, my colleagues of the Royal Society, for electing me five times to be your President, for

forgiving me all my short-comings, and for the inestimable benefit which you have conferred on me by giving me your friendship.

In the evening a large number of the Fellows and their guests dined together at the Hôtel Métropole. Among those present being M. Marey, who attended officially as President of the Paris Academy of Sciences.

DR. DUBOIS' "MISSING LINK."

THE opening scientific meeting of the session of the Royal Dublin Society, on November 20, was of especial interest, owing to the presence of Dr. Eugene Dubois, who exhibited the famous remains which he discovered in Java. The chair was taken by Prof. W. J. Sollas, F.R.S. Dr. Dubois read a paper "On *Pithecanthropus erectus*: a transitional form between Man and the Apes," which will very shortly be published by the Society, and which was illustrated by a number of lantern slides made in Dublin for this lecture. He said that when he was invited by Prof. Cunningham to read a paper before the Royal Dublin Society, he did not for a moment hesitate to comply, as he was anxious to get as much criticism as possible. By order of the Dutch Indian Government he conducted, from 1890 to 1895, explorations of a fossil vertebrate fauna, of which some remains had been discovered many years ago by Junghuhn and others. These vertebrate remains, which were found abundantly at Trinil on the southern slope of the low Kendeng Hills, were obtained from beds of cemented volcanic tuff, consisting of clay, sand and consolidated lapilli, which were rearranged by fluviatile action. The whole formation attains a maximum thickness of over 350 metres. In these strata the Bengawan River has cut its channel 12 to 15 metres in depth. These beds lie unconformably upon beds of marine marl, sand and limestone, which have recently been determined by Prof. Martin to be of Pliocene age. In August 1891, Dr. Dubois came upon a very rich layer of fossil bones, in which the remains in question were found; this occurred in the lapilli deposit, or fine gravel, about five inches above a bed of coarse gravel, which rests on a black clay. The layer of bones lies a little below the dry-season level of the river. The river-bank was excavated with such care that the position of each specimen was accurately known. In September a wisdom tooth was discovered, and a month later the skull-cap was found about one metre distant, and at precisely the same level. The work was interrupted by the rainy season, but was renewed in May 1892; the left femur was found in August, at distance of about 15 metres from the calvaria, and in October a second molar, at a distance of 3 metres from where the skull-cap was found, and in a direction towards the place where the femur had been dug out. Among the associated animals may be mentioned large numbers of Stegodon, specimens of hippopotamus (Hexaprotodon), hyæna, several species of deer, Bubulus, a gigantic pangolin three times as large as the existing Javan form, &c. The four remains were all in the same state of fossilisation as the animal remains, the weight of the femur being nearly three times that of a recent femur. Doubt had been expressed whether the four remains belonged to the same individual; Dr. Dubois himself had no doubt on this point, as he had often found bones from the self-same skeleton, and even fragments of a single bone, at similar distances apart; never had he found a complete skeleton. He had good reasons for believing that the animals perished in volcanic catastrophes, and their corpses were brought down a large Pliocene river, so that before the bones were finally deposited and buried they must have been separated by the rotting of the flesh; and there are evidences of crocodiles having preyed upon the carcases.

The femur is so human-like that nearly all anatomists did not hesitate to declare it to be human; but up to the present no human remains had been found in the Lower Pleistocene, the oldest only reach down to about the middle of that period. Nobody had the slightest doubt that the bone must have belonged to a form with an erect posture. Only Virchow repeatedly maintained, even after seeing it, that it belonged to an ape, probably Hylobates, because it has, in his opinion, a straight, shaft such as never occurs in man; but the audience could easily see that the shaft of the fossil was by no means straight, and Dr. Dubois demonstrated some features which he had never seen in human femora, but which he believed to be simian characters.

For normal human proportions the capacity of the cranium was too small for the femur; but microcephalic skulls of the class which may be regarded as atavistic can be even relatively smaller, while the height of the body is more than that of Pithecanthropus, as computed from the length of the femur. Such was the case of the microcephalic idiot, Joe, described by Prof. Cunningham. The length of the Java cranium is 185 mm., its breadth 130 mm. The same dimensions in an average female chimpanzee's skull are 132 and 91, and those of a Hylobates 95 and 69. The internal capacity he estimated at 1000 cubic centimetres. The largest skulls of the anthropoid apes average about 500 c.c. Normal human skulls are known of an equal or even less size than the Java cranium; but these small skulls are always associated with a small body. The chances are enormously against this being the skull of an idiot, and no microcephalic skull shows such a flattening of the parietal region. The orbital part of the skull is quite different from that of man, but the inclination of the nuchal plane is far more human than simian. From the genus Hylobates he could only find a difference in size and in the downward slope of the occiput; the resemblance between the two was most striking if the former was enlarged two diameters.

A divergence of opinion also prevailed as to whether the teeth were human or simian; they were larger than human teeth, and the cusps showed a relative development which was characteristically simian.

From the whole geological and anatomical investigation it followed that in each of the four specimens they had evidence of a form intermediate and transitional between man and anthropoid apes. The problem was as to the exact position of this creature in the tree of genealogical descent.

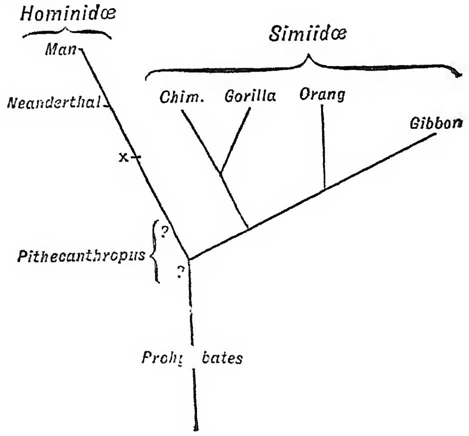
Dr. D. J. Cunningham, Hon. Secretary of the Society, believed the specimens to be of supreme importance. Discussing Dr. Dubois' memoir at a previous meeting of the Royal Dublin Society, he had expressed the view that the cranium was distinctly human, and he still held that an unbiassed study of the published description and figures could lead to no other conclusion. Now, however, when he was brought face to face with the actual specimen, he failed to see in it any decided and leading human feature, except its capacity of 1000 c.c. He agreed with Dr. Dubois in considering that it most resembled the cranium of Hylobates, although he was of opinion that Dr. Dubois slightly exaggerated the relative height and quality of the cranial arch in Hylobates. In this respect he considered that, if fairly tested, the fossil cranium would be found to be superior to any known ape. Certainly the cranial arch was vastly superior to that of a gorilla, chimpanzee, or orang, and he believed also that it was relatively fuller and loftier than the most highly-arched Hylobates cranium. Dr. Dubois placed some stress upon the inclination of the nuchal area of the occipital bone, and thought that in this there was a human characteristic; but he (Dr. Cunningham) thought that this region of the cranium was extremely ape-like, and, further, he did not altogether consider that the means which Dr. Dubois had taken to determine the degree of this inclination were calculated to yield absolutely trustworthy results.

With regard to the femur, he had nothing to add to what he had previously said on this subject. It was a human bone, and while he fully appreciated the distinctive points alluded to by Dr. Dubois, he thought that Dr. Dubois had not made sufficient allowance for the variation to which this bone was liable. It was, to say the least of it, strange that a thigh-bone of such undoubted antiquity should exhibit none of those characteristics which we were in the habit of associating with prehistoric femora, as well as with the femora of rude and savage races of the present day. It showed no signs which would indicate that the individual to whom it belonged was in the habit of assuming the squatting attitude.

In so far as the two molar teeth were concerned, he still held that the features which they exhibited were more human than simian, although it could not be denied that they also exhibited some very decided ape-like characters.

The question as to the place which should be assigned to the fossil form on the genealogical tree was a most interesting one. On this point he differed entirely from Dr. Dubois. Dr. Dubois placed Pithecanthropus below the point of devarication of the anthropoid apes from the human line. Dr. Cunningham, on the other hand, placed it on the human line, a short distance above the point at which the anthropoid branch is given off. In urging this view, he stated that he could not believe that an ape-form with a cranial capacity of 1000 could be the progenitor of the man-like apes, the largest of which had a capacity of only 500.

Such a supposition would necessarily involve the assumption that the anthropoid apes were a degenerated branch from the common stem. This view he explained by means of the accompanying diagram.



Prof. Haddon said: Ever since the evolution hypothesis had shed such an illumination upon nature, biologists had believed in the previous existence of forms intermediate between man and the lower animals; and it was with a fearful joy that they heard of Dr. Dubois' discovery, and then they subjected the remains to a searching criticism, with the result that all agreed that the individual to whom the cranium belonged was transitional in character between the apes and man—some thinking him more ape-like, and others more human; balancing the one set of opinions against the other, they could only come to the opinion that it was an intercalated type. Whilst agreeing with Dr. Dubois in all his statements of fact, he concurred with Prof. Cunningham in thinking that the size of the cranium was an insuperable difficulty in the way of placing the individual to which it belonged below the point in the genealogical tree where the anthropoids branched off. Palæontological evidence points to the fact that in the evolution of any series of mammals the brain tends to increase in size; at all events, there is no known case of a brain decreasing to less than half its original dimensions. Nor did it appear to him to meet the case to suppose that by doubling the body of a gibbon the brain would be equally doubled in size; there was no such proportion between body growth and brain growth.

Dr. Pearsall, a leading dental surgeon in Dublin, made some remarks about the teeth, and said that the human characters of the teeth were very striking.

Prof. Sollas agreed with the preceding speakers as to the invaluable evidence afforded by these fossil remains. They indicated an organism which was either a pithecoid man or a remarkably human ape; which of these alternatives might prove to be true was a matter of secondary importance, the fact remained that we had before us traces of the most simian ancestor of the human race yet known.

The materials for determining its geological age were abundant, but not yet fully worked out. Dr. Dubois, however, stated that the associated mammalian fauna stood in close relation to that of the Nerbada beds and the Upper Siwaliks of India; and so far as it might be possible to correlate the Javan deposits with those of Europe, they would appear to be older than our river-drifts, and possibly on the same horizon as the forest-bed of Norfolk. In this case the intervals in time, and the differences of structure which separate the Javan fossils from the race of Spy, and this from existing man would be, so to speak, proportional.

In the Miocene times we first meet with a few modern genera struggling to the front from a crowd of competitors; and in the Pliocene a few modern species emerge, and thus, in the case of the human race, we might expect to find the existing species *Homo sapiens* replaced by some earlier representative, say *Homo innocens* in the Pliocene, and the genus *Homo* by allied though different genera of the family *Hominidæ* in the Miocene. While, however, *Hominidæ* are not yet known from the Miocene, remains of anthropoid apes (*Dryopithecus*) are, and thus what palæontological evidence exists lends no favour to the view that the anthropoids are degenerate descendants from the human stem. Thus Prof. Sollas was less inclined to agree with Dr. Dubois than with Prof. Cunningham in estimating the human characters of the Javan fossils.

Dr. Dubois thanked the Society for the honour they had done him and for their kindness. He explained why he placed Pithecanthropus in a different position in the genealogical tree from that assigned to him by Prof. Cunningham. They knew very little about the laws of evolution, which in some cases proceeded slowly and in others quickly.

The proceedings then terminated.

SCIENCE IN THE MAGAZINES.

SEVERAL articles on more and less scientific topics appear in the *Contemporary*. Mr. Herbert Spencer contributes the seventh of his series of articles on the development of professional institutions, the subject this month being the teacher. It is shown that the primitive conception of the teacher is the conception of one who gives instruction in sacred matters, so that the priest and teacher were identical. The priesthood is, for a long time, the sole source of knowledge, but in the course of evolution the teaching functions of the priest are shared by a non-priestly class, and thus the secular educator comes into existence. Mr. Spencer quotes, in support of this theory of development, extracts from the records of peoples, past and present, in various parts of the world. The evidence adduced goes to show "how teaching was in the beginning exclusively concerned with religious doctrines and rites, and how there eventually began to rise a teaching which, in some measure detached from the religious institutions, at the same time entered upon other subjects than the religious." In some cases, the normal genesis of teachers from priests was interfered with, but that does not alter the general fact of such development. The differentiation of the teaching class from the priestly class is even now incomplete, for a large number of the private schools in our own kingdom are carried on by clergymen. Finally, as in other professions, segregation and consolidation into unions and associations have followed upon differentiation.

M. Berthelot, the renowned chemist, lately appointed French Minister for Foreign Affairs, was a close friend of Renan. A few incidents referring to that friendship, and what Renan might have thought of the appointment, are given in the *Contemporary* by Mr. Albert D. Vandam. The same review contains the first instalment of an article on "Physics and Sociology," by Mr. W. H. Mallock. The character of the article is sufficiently indicated by the following headings of the sections. (1) On the application to social phenomena of the methods and principles derived from physical science; (2) on the crucial difference between the subject-matter of physical science and that of social science, which render the method of study proper to the first inadequate when applied to the second; (3) on the deliberate rejection by contemporary sociologists of the methods by which, in social science, the methods of physical science must be supplemented; (4) on the nearness with which contemporary sociologists have approached the methods of study, which they have nevertheless missed or rejected. The *Contemporary* also contains articles on the Secondary Education Report, by Prof. J. Massie; Mr. Balfour's philosophic writings, by Mr. Norman Hapgood; and a reply, by Prof. A. A. Bevan, to an article in which Prof. Sayce dealt with Biblical criticism from an archæological point of view.

The first number of the English series of the *Popular Science Monthly* contains a large amount of readable matter on scientific topics. Accompanying a description, by Mr. H. P. Fitzgerald Marriott, of the Palæolithic skeletons discovered near Mentone in 1892 and 1894, are three good illustrations reproduced from photographs of the remains. Prof. Sully contributes an interesting paper entitled "Studies of Childhood," and there are also popular articles on consumption, the saltness of the sea, and other subjects. We notice a letter entitled "Are Animals Left-handed?" by Mr. D. S. Jordan. Several observers have stated that parrots grasp and hold food with the left claw, but Mr. Jordan concludes from his observations that "the appearance of left-footedness is due entirely to the fact that those who offer the finger or food to parrots do so as a rule with the right hand. Repetition of this process makes the parrot more or less left-footed in time."

Lieut. B. Baden Powell describes his "Air-Car, or Man-

lifting Kite" in the *National*, and expatiates upon its superiorities over the balloon. The machine consists of a varying number (usually four or five) of sails of a flattened hexagonal shape. These are connected, one behind the other, to the ground-line, from which latter is suspended a basket-car, which has a parachute spread out above it in case of accident. The number of kites required to lift the car depends upon the wind. Lieut. Powell has tried his kites on several occasions, once during the meeting of the British Association at Ipswich, and though the result has in a few cases been disappointing, yet on the whole they have been very successful. To sum up, he remarks: "We have here a machine capable of lifting a man safely to a height, which has many advantages over a balloon. It is infinitely more portable; it is infinitely less costly. It requires no reserve supplies, and is not precluded from ascending by too much wind. It is practically invulnerable, and it promises to be of use in many circumstances rendering a balloon impracticable." What Lieut. Baden Powell specially wants is that the War Department, or the Treasury, should thoroughly investigate his invention and completely put it to the test. Our present Army Balloon establishment costs £3000 a year, and Lieut. Powell thinks most of this would be saved if the air-car were used, and with no loss of efficiency.

In a long paper contributed to the same *Review*, Mr. Mortimer Granville gives to the world "A New Theory of Gout." It is for students of chemical physiology and pathology to estimate the value of the evidence brought forward; all we need do is to indicate the kind of conclusions arrived at, viz.: (1) That gout is not a malady having for its cause an over-production of uric acid. (2) Gout is a malady which has for its cause the presence in the organism of an undue proportion of leucocytes, not necessarily in the blood, but in the organs and tissues generally. (3) If this view of gout be the true one, the treatment of the malady must be the treatment of leuchæmia or anæmia. In other words, efforts should be made, by means of a meat diet, to multiply the red corpuscles in the blood, and so assist in bringing about a reduction of the white corpuscles—uric acid makers—within normal limits.

In *Scribner's Magazine*, under the title "Wild Beasts as they Live," Captain C. J. Melliss, a well-known authority on lion and tiger hunting, describes those animals from a sportsman's point of view, his article being illustrated by reproductions from a remarkable series of etchings of wild animals, by Evert van Muyden. Among the articles in *Knowledge*, we notice "The Filtration of Water," by Dr. S. Rideal; "Whip Scorpions and their Ways," by Mr. R. I. Pocock; and "New Stars," by Dr. A. Brester.

A passing reference must suffice for the remaining articles on scientific subjects in the magazines received by us. A paper on "The Limits of Natural Selection," contributed to the *Humanitarian* by Prof. C. Lloyd Morgan, is accompanied by a portrait of the author. A description of the arrangements made for the International Exhibition of 1900, with a plan showing where the exhibition will be placed, how the grounds will be divided, and what will be the names of the principal buildings, is given in the *Century*. Mrs. Lecky has in *Longman's* a very interesting account of the Institute of France, and the recent centenary celebrations. Among the subjects of popular articles in *Chambers's Journal*, we notice "The Metal Platinum," "Living Barometers," "Ivory," "Our Simian Cousins," "The Ancient Incas of Peru."

In addition to the magazines mentioned in the foregoing, we have received the *Fortnightly Review*, *Strand Magazine*, *Good Words*, and the *Sunday Magazine*, but no articles in them call for comment here.

SCIENTIFIC INVESTIGATIONS OF THE FISHERY BOARD FOR SCOTLAND.

THE part of the thirteenth annual report of the Fishery Board for Scotland, dealing with the principal scientific investigations carried on in 1894, in connection with the sea fisheries under the charge of the Board, has recently been issued. An idea of the scope and value of the work done may be obtained from the following summary:—

In the course of the year, the investigations, which were carried out under the supervision of Dr. T. Wemyss Fulton, were prosecuted on the same general lines as in previous years, and have resulted in further extensions of knowledge respecting the life-histories and habits of the fishes which form the basis of the fishing industry, and of the operation of certain methods of fishing in relation to the food supply. Besides such inquiries, which are necessary for the proper conservation and regulation of sea fisheries, the operations in the hatching and artificial propagation of some of the more important food fishes have been continued at Dunbar Marine Hatchery, which was completed last year, and which have resulted in the addition of over forty-five millions of the fry of plaice, turbot and cod to the fishing-grounds along the neighbouring coast. Similar establishments are now in operation in the United States, Canada, Newfoundland and Norway, and others are in process of being formed in France and in Lancashire.

As in previous years a large part of the scientific inquiries, both biological and physical, have been carried on or rendered possible by means of the *Garland*, the small steamer obtained by the Board for this work; but, as has been mentioned in previous reports, her small size has curtailed the extent and usefulness of the investigations.

Part of the scientific work was also carried on at the marine laboratories at St. Andrews and Dunbar.

THE HATCHING AND REARING OF FOOD FISHES.

In last year's report the reasons which induced the Board to establish a hatchery for sea-fishes at Dunbar were given, together with a detailed description and plans of the building, and an account of the work during the first season it was in operation. The present report contains an account by Mr. Harald Dannevig, who is in charge of the hatching work, of what has been accomplished during the current season, and of the work now in progress. It is satisfactory to be able to note that the various pumping and incubating apparatus have continued to work well and without any hitch, and that the number of fry of the food fishes which have been successfully dealt with this season considerably exceeds the number turned out last year.

The great majority of the young food fishes which have been propagated have consisted of plaice, of which 44,085,000 eggs were obtained from the spawning pond, yielding 38,615,000 fry. The number of cod hatched numbered 2,760,000, and the number of turbot 3,800,000. This seems to be the first time that the eggs of the turbot have been hatched at any hatchery, and the success in this respect has enabled the development of this important fish to be studied and described by Prof. M'Intosh.

In regard to the practical results of marine pisciculture in adding to the fish supply, it may be stated that in the United States, Newfoundland and Norway—where cod alone has been propagated on a large scale—according to the official reports published in these countries the abundance of young cod has been materially increased. In the neighbourhood of the hatchery on Dildo Island, Newfoundland, the shoals of this fish were so numerous during the past season that they were described as a "solid thick mass covering the bottom for long distances on both sides of the island," and it is stated that fishermen from other parts, on hearing of the abundance of cod, came to Dildo to fish. Sufficient time has not, of course, elapsed since active operations were begun at Dunbar to afford any indication as to the influence of the work in increasing the fish supply, but there are some points of importance that may be considered in connection with the subject. There can be no doubt that the great majority of the fry distributed on the fishing grounds are destroyed from natural causes; but if only a fraction of one per cent. survive, the resulting benefit would far exceed the expenditure upon the work. If one in a hundred of the fry distributed from the hatchery survived, and if the price of the marketable fish be placed at sixpence, the resulting value to the fisheries would be about £18,000. It would require the survival of only one in a thousand, and the marketable fish to be sold at only one penny each, to cover the expenses of the work.

THE INFLUENCE OF MARINE CURRENTS IN TRANSPORTING FLOATING EGGS AND LARVÆ FROM OFFSHORE SPAWNING AREAS.

Previous investigations have shown that the inshore waters are destitute of spawning grounds for the great majority of the food fishes, and that they receive their supplies from the spawning areas situated at some distance from shore. In the present report a preliminary account is given, by Dr. T. Wemyss Fulton, of experiments which have been made to determine the influence of marine currents in transporting the floating eggs and young fishes to various parts of the coast. It is shown that they may be carried in the course of their development long distances in a

definite direction, to other parts of the coast, and that the fish supply of a given area of the territorial waters on the east coast may be derived, not from the spawning areas *ex adverso*, but from those situated further north.

THE LIFE-HISTORIES AND DEVELOPMENT OF THE FOOD FISHES.

The report contains an important paper by Prof. M'Intosh, giving the results of his continued investigations on the eggs, young, and development of several of the food fishes, the work having been carried on, as in previous years, at St. Andrews Marine Laboratory. The principal investigation relates to the development of the turbot, which has now for the first time been elucidated, fertilised eggs having been procured from the hatchery. The ripe egg of the turbot has an average diameter of 1·0287 mm., and is perfectly buoyant, floating at the surface of still water or suspended midway, and it possesses a prominent oil-globule. The embryonic fish, which is of a reddish colour, emerges from the egg about the sixth or seventh day, so that the period is short before hatching occurs. The larvæ in a few days become active and dart rapidly through the water, and they are hardy; the yolk-sac becomes absorbed about the seventh day, and thereafter they feed for themselves, being extremely quick in noticing the movements of the minute crustaceous and other forms in the water around them. Prof. M'Intosh states that no form hitherto observed at St. Andrews appeared to be more hardy, or to undergo the vicissitudes of temperature and manipulation with greater impunity than the young turbot; there are grounds, therefore, for expressing the hope that they may yet be reared in great numbers from the post-larval to the adolescent and adult condition in suitable enclosures. The various stages in the development of this valuable form are described and figured. Another species whose development is described is the long rough dab, the pelagic eggs of which are found in considerable abundance in March and April.

Mr. H. Charles Williamson contributes an elaborate paper on the reproduction of the common eel, which has been, and still is, in many respects, involved in considerable obscurity. He gives a very full account of the reproductive organs, both as described by other naturalists, and as observed by himself in a number of specimens examined at St. Andrews; and the paper includes a description of the migrations of the eel, and all that has been ascertained about its spawning. It is a remarkable fact that the ripe egg of the eel has never yet been discovered.

Mr. Williamson also gives a detailed account of the distribution of the pelagic eggs and larvæ of various species of food fishes, obtained in tow-nets, including those of the plaice, haddock, cod, whiting, saithe, sprat, dab, turbot, gurnard, long rough dab, flounder, &c. In another paper he describes the variation in the size of the eggs of a number of the food fishes. Dr. Fullarton has also furnished an elaborate description of the larval and post-larval development of the brain in the lesser sand-eel (*Ammodytes tobianus*), accompanied by illustrations. The important subject of the rate of growth of fishes is at present receiving considerable attention in connection with fishing questions. In the present report Mr. Arthur T. Masterman gives the result of his researches on the subject at St. Andrews, dealing especially with the rate of growth of the plaice.

Mr. Harald Dannevig also furnishes an account of the experiments he has made in regard to the influence of variations of temperature in accelerating or retarding the development of the eggs of fishes. The species dealt with were the plaice, cod, haddock, whiting and flounder.

Finally, the report contains a paper, by Mr. Thomas Scott, on the fauna of the Firth of Forth area and of inland waters; Mr. A. J. Herbertson contributes an elaborate paper, accompanied by numerous tables, dealing with the physical observations on the temperature and density of the sea; and Dr. Wemyss Fulton gives an account of the scientific fishery work and the condition and regulation of the sea fisheries in other countries possessing them, and of the principal methods employed to protect and develop them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. A. R. Forsyth, F.R.S., Sadlerian Professor of Pure Mathematics, has been appointed by the Council of the Senate a member of the Governing Body of Eton College, in the room of Dr. Ferrers, F.R.S., resigned.

An Isaac Newton Studentship in Astronomy and Physical Optics will be vacant in the ensuing Lent term. The studentship is of £200 per annum for three years. Candidates must be at least B.A.s of the University, and under the age of twenty-five on January 1, 1896. Their names should be sent to the Vice-Chancellor between January 14 and 24 next, together with statements as to course of study or research proposed in each case.

The Observatory Syndicate report that they have abandoned the expectation of receiving public subscriptions for the proposed photographic telescope. They now contemplate the erection of a triple apochromatic telescope, the objective of which is to be furnished by Messrs. Cooke, of York, at a cost of £550. The tube of the instrument will be hinged, the larger part of the tube with the eye-piece lying in the polar axis. The rays from the objective at the end of the short movable part of the tube will fall on a flat mirror at the hinge, and be thence reflected to the eye-piece. The flat mirror will be furnished as a gift by Dr. Common, and Sir Howard Grubb is to be entrusted with the construction of the tube at a cost of £1100. The necessary moneys it is proposed to draw from the Sheepshanks Funds, and the Syndicate ask the Senate to sanction this appropriation.

Prof. Ewing, F.R.S., has been appointed Chairman of Examiners for the Mechanical Sciences Tripos, 1896. Among the annual appointments of members of the various Boards and Syndicates are the following:—Mr. Glazebrook, F.R.S., General Board of Studies; Mr. W. Gardiner, F.R.S., and Mr. W. Bateson, F.R.S., Botanic Garden Syndicate; Mr. Love, F.R.S., Library Syndicate and Observatory Syndicate; Mr. Heycock, F.R.S., Museums Syndicate; Dr. Hobson, F.R.S., Proctorial Syndicate, and Mathematical Board; Mr. Capstick, Highest Grade Schools; Prof. Bradbury and Dr. Shore, State Medicine; Dr. D. Hill, Agricultural Science; Mr. Shaw, F.R.S., Fire Prevention, and Board for Physics and Chemistry; Dr. A. MacAlister, Special Board for Medicine; Dr. Gaskell, F.R.S., Board for Biology and Geology.

It is proposed to invite representatives of the chief educational authorities and institutions to meet in Cambridge during the ensuing Long Vacation, in order to confer on questions arising out of the Report of the Royal Commission on Secondary Education. The Vice-Chancellor, on behalf of the University, will convene the conference.

THE Calendar of the University College, Nottingham, for the fifteenth session, 1895-96, has been issued.

THE following are among recent appointments:—Dr. J. Munk to succeed Dr. Gad at the Berlin Physiological Institute; Dr. Paul Kempf and Dr. Wilsing, of the Potsdam Astrophysical Observatory, to be Professors; Prof. Theel, of Stockholm, to be Director of the Natural History Museum there; Dr. Strahl, of Marburg, has been appointed to the chair of Anatomy in Giessen University.

THE *London Technical Education Gazette*—the official organ of the Technical Education Board of the London County Council—contains the following satisfactory announcement:—"It has been part of the policy of the Technical Education Board in connection with higher education, and will be, if possible, through the proposed Teaching University of London, when that University is established, to secure for students who can devote their evenings only to study, a course of instruction of the highest type in all branches for which provision is now made for day students in the universities and university colleges, and to provide that the teachers of these classes shall be the same professors as take the day classes, or others of equal standing. As a step in this direction the Board has arranged with the authorities of University College for the conduct of four courses of lectures and practical work in the departments of Mechanical Engineering, Electrical Engineering, Chemistry, and Applied Mathematics."

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, November 7.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—On flame temperatures and the acetylene theory of luminosity, by A. Smithells. The author criticises adversely Lewes's theory of the luminosity of hydrocarbon flames on the ground of ex-

perimental evidence.—A new series of hydrazines, by F. D. Chattaway and H. Ingle. The quaternary hydrazines of the general formula $R_2N.NR_2$ may be prepared from secondary amines by acting on the sodio-derivatives of the latter with iodine.—The action of certain acidic oxides on salts of hydroxy-acids (part ii.), by G. C. Henderson and D. Prentice. A number of crystalline compounds of antimonious and arsenious oxides with salts of citric, malic and mucic acids have been prepared.—Sodium nitrososulphate, by E. Divers and T. Haga.—The constitution of nitrososulphates, by E. Divers and T. Haga. In these two papers the authors detail evidence showing that the nitrososulphates are true sulphates of the constitution $RON_2.O.SO_3K$.—Normal hexane from light petroleum (petroleum ether), by G. L. Thomas and S. Young. Employing their recently described form of dephlegmator, and treating the fractions with mixed nitric and sulphuric acids, the authors have been able to separate an almost pure sample of normal hexane from light petroleum.—The vapour pressures, specific volumes and critical constants of normal hexane, by G. L. Thomas and S. Young. The critical temperature, pressure and volume of a gram of synthetic normal hexane are 234°.8, 22510 mm. and 4·268 c.c. respectively: the oil boils at 69°·0 under 760 mm., and has the specific gravity 0·67696 at 0°.—Acidylthiocarbimides, by A. E. Dixon.—Some constituents of the root of *Polygonum cuspidatum*, by A. G. Perkin. From the roots of this plant, which is a native of China and Japan, the author has separated a new glucoside, cuspidatin, $C_{21}H_{20}O_{10}$, which yields emodin on hydrolysis; a second glucoside, emodin, and a wax were also isolated.—Note on the action of hydrofluoric acid upon crystallised silicon, by G. S. Newth. Gaseous hydrogen fluoride causes the ignition of warm crystallised silicon.—Note on the periodides of theobromine, by G. E. Shaw. The author has prepared four new periodides of theobromine and its hydrochloride.—A synthesis of diphenyloxytriazoline, by G. Young.—Note on piperovatine, by W. R. Dunstan and F. H. Carr. Piperovatine may be rapidly extracted from *Piper ovatum* by percolating the material with ether.—Dibenzaconine and tetracetylaconine, by W. R. Dunstan and F. H Carr.—Molecular volume change during the formation of dilute solutions in organic liquids, by A. W. Jones. A series of determinations of the volume changes occurring when a number of liquids are dissolved in benzene and carbon disulphide have been made.

Royal Meteorological Society, November 20.—Mr. R. Inwards, President, in the chair.—A paper by Mr. J. Eliot, F.R.S., was read, on the origin of the cold weather storms of the year 1893 in India, and the character of the air movement on the Indian seas and the equatorial belt, more especially during the south-west monsoon period. This was really a discussion of the data contained in the *Indian Monsoon Area Charts*, the publication of which was sanctioned by the Indian Government for the two years 1893-4. Cyclonic storms are of frequent occurrence during both the north-east and the south-west monsoons, but they differ in many important respects. The storms of the south-west monsoon originate almost invariably over a sea surface, and travel in very variable directions, and occasionally develop into intense and furious hurricanes. The cyclonic storms of the north-east monsoon almost invariably originate over the plateau of Persia or Baluchistan, or in North-Western India, and travel in an easterly direction at a velocity ranging between fifteen and twenty miles per hour. These plateau-formed storms of the cold weather are the chief instruments of the distribution of the moderate rainfall essential for the great cold weather wheat and other crops of Northern India, and are the chief sources of the snowfall of the Western Himalayas. After giving an account of the more important cold weather storms in January and February 1893, and the results of the tabulation of the wind observations for the equatorial belt, the author describes the "burst of the monsoon." Mr. Eliot says that the evidence of the year 1893 is strongly in favour of the supposition that the south-west monsoon currents in the Indian seas are the direct continuation north of the equator of the horizontal movement of the south-east trade winds; and that the larger variations in the strength of the south-east trades near the equator during the monsoon period are reproduced in the monsoon currents in the Indian seas from June to September.—Mr. W. H. Dines showed an interesting experiment to illustrate the formation of the tornado cloud. The characteristic funnel cloud was readily seen extending from the tray of hot water to the mouth of the pipe at the top of the box, and when the draught was strong and the conditions favourable, a decided protuberance was observed on the surface of the water just under the end of the cloud. Mr. Dines is of opinion that the cloud is formed by true dynamic cooling as the air, saturated by the vapour from the hot water, comes under the influence of the decreased pressure at the centre.—A paper by Mr. C. Davison was also read, on the diurnal variation of wind velocity at Tokio, Japan.

Malacological Society, November 8.—Prof. G. B. Howes, President, in the chair.—The following communications were read:—Descriptions of new species of terrestrial and fluviatile mollusca from the Hadramaut, South Arabia, by J. C. Melvill and J. H. Ponsonby.—Notes on the anatomy of *Hanleya abyssorum*, M. Sars: (*a*) on the presence and position of an osphradium; (*b*) general notes, by R. H. Burne.—Description of a new species of the genus *Cassis*, by G. B. Sowerby.—Description of a new species of *Vitrina* and new forms of *Helicidæ* together with a list of the Helicoid land-shells hitherto found in the Canary Islands, by G. K. Gude.—Description of a new species of *Streptaxis*, by G. K. Gude. Specimens in illustration of their respective papers were exhibited by the authors.—Mr. Da Costa exhibited a series of land-shells from the Galapagos Islands. Mr. Moss exhibited a white *Helix perplexa*, Fér., from Grenada.—Mr. Sykes exhibited land-shells from a deposit at Blashenwell, Dorset.

PARIS.

Academy of Sciences, November 25.—M. Marey in the chair.—On para-ethoxyquinoline, by M. C Grimaux. The production and properties of para-ethoxyquinoline and some of its derivatives are described Conforming to Skraup's nomenclature, the name quinethol is given to this substance and its derivatives are termed nitroquinethol and amidoquinethol.—Observations of small planets, made with the great equatorial of Bordeaux Observatory, by MM. G. Rayet, L. Picart, and Féraud.—M. Lannelongue has been nominated by vote as member of the Medicine and Surgery Section of the Academy.—The rapid estimation of nitric nitrogen in vegetable products, by M. P. Pichard. The method is a colorimetric process based on the colouration produced when nitric acid acts on brucine.—Observation of the new comet Perrine (November 16, 1895), made at Marseilles Observatory, by M. Esmiol.—The polar snows of Mars, by M. Camille Flammarion. A comparison of some observations by the author with observations recorded at Lick Observatory.—On the displacement of a trihedral trirectangle around its summit, the position of this trihedral figure depending on two parameters, by M. Maurice Fouché.—On the electro-capillary properties of dilute sulphuric acid, by M. Gouy.—Action of phenol on mercurous iodide, by M. Maurice François. It is shown that phenol has a similar action on mercurous iodide to that of aniline. A certain proportion of the salt is decomposed to mercuric iodide and mercury until a state of equilibrium is set up between this action and the reverse action. Equilibrium obtains when 100 grams of solution contain 2·75 grams of mercuric iodide.—On manganese silicide, by M. Vigouroux. The compound $SiMn_2$ has been produced (1) by the direct action of silicon on the metal, (2) by the action of silicon on the oxide, (3) by the action of carbon on a mixture of silica and oxide. It is a very hard and sonorous substance of metallic lustre, and perfectly crystallised. Its aspect is steel-grey, density at 15° = 6·6, and it is unalterable in the air and fusible at the temperature of the reverberatory furnace. The chemical properties are given in detail in the paper.—On the toxicity of acetylene, by M. L. Brociner. A note calling attention to some of the author's work published in 1887, and prior to the recent publication on this subject of M. Gréhant.—On some reactions of tartaric acid and alkaline tartrates, by M. L. Magnier de la Source.—On the morphological interpretation of double larvæ in composite Ascidians of the genus *Diplosoma*, by M. Maurice Caullery.—On the effects produced on the rabbit and pigeon by the extraction of the stapes or of the columella and the experimental lesion of the membranous vestibule, by M. Garnault.—Laccase in fungi, by MM. Em. Bourquelot and G. Bertrand.—On the distribution of nitrogenous and mineral matters in bread, by M. Balland.

BERLIN.

Physiological Society, October 25.—Prof. du Bois Reymond, President, in the chair.—Dr. René du Bois Reymond gave an account of experiments made in repetition of Martin's, on the action of the internal intercostal muscles. He confirmed the

conclusions arrived at by this investigator, but he more particularly limited his experiments to an examination of the internal intercartilaginous intercostals. It appeared that the latter, in opposition to the expiratory action of those between the ribs, have an inspiratory function, and contract synchronously with the diaphragm. After an artificial apnœa they enter again into activity at a slightly later period than does the diaphragm, resembling in this the inspiratory external intercostals. Dr. Rawitz recommended the employment of a very dilute solution (three to five drops of the concentrated ammoniacal solution in 30 to 50 c.c. of distilled water) of either hæmatoxylin or hæmatein, when these are used for staining, either alone or as subsequent to the use of eosin. The sections should lie in this solution for twenty-four to forty-eight hours. He then spoke on the use of alizarin and alizaro-cyanin for histological purposes. These substances can only be used with a mordant, of which a chromium salt was found to be most efficient with the former stain, and a salt of iron with the latter. In this way very brilliant permanent stainings may be obtained, which are particularly suited for the investigation of nuclear division.—Dr. Benda exhibited some striking preparations of neuroglia, obtained by a method to be described later on.

Physical Society, November 1.—Prof. du Bois Reymond, President, in the chair.—Dr. Claude du Bois Reymond exhibited specimens of colour-photographs, made by Dr. Joly, of Dublin, and described how they had been obtained. Dr. Rubens gave an account of experiments made by D. C. Cole on the refractive index of water and alcohol for electrical rays of short wave-length. Having failed to obtain any results with a prism for rays of 5 cm. wave-length, he used Fresnel's formula and the reflexive powers of these fluids for vertical and parallel polarised rays. In this way he found that for water the coefficient for rays of the above wave-length is the same as for rays, as previously investigated, of 10 cm. and of 60 cm. In the case of alcohol it was markedly less for rays of shorter than for those of greater wave-length. The method was also applied to petroleum, and gave results similar to those previously obtained for this liquid by other methods.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, DECEMBER 5.

ROYAL SOCIETY, at 4.30.—Studies in the Morphology of Spore-producing Members. Part II. Ophioglossaceæ: Prof. F. O. Bower, F.R.S.—On the Weight of a Cubic Decimetre of Water at its Maximum Density: Prof. Mendeleeff, For. Mem. R.S.—The Measurement of High Potential Difference: H. C. Leake, R. Leventhorpe, and C. S. Whitehead.—Variations in the Electromotive Force of Clark Cells with Temperature: Prof. Ayrton, F.R.S., and W. R. Cooper.

LINNEAN SOCIETY, at 8.—On a New Species of Bromus in Britain: G. C. Druce.—Notes on New or Rare Phasmidæ in the Collection of the British Museum: W. F. Kirby.

LONDON INSTITUTION, at 5.—Old Musical Instruments: A. Dolmetsch.

CHEMICAL SOCIETY, at 5.—The Constitution of Terpenes: Prof. Armstrong, F.R.S.—New Derivatives from α-dibromo Camphor: Dr. M. O. Forster. The Chemistry of Dibromopropyl Thiocarbimide, and the Action of Bromine and Iodine on Allyl Thiourea: Prof. A. E. Dixon.—Ballot for the Election of Fellows.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, DECEMBER 6.

GEOLOGISTS' ASSOCIATION, at 8.—Notes on Indian Geology, including a Visit to Kashmir: W. H. Hudleston, F.R.S.

QUEKETT MICROSCOPICAL CLUB, at 8.

SUNDAY, DECEMBER 8.

SUNDAY LECTURE SOCIETY, at 4.30.—Lecture by Sir B. J. Richardson, F.R.S.

MONDAY, DECEMBER 9.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Exploration in the Central Alps of Japan: Rev. Walter Weston.

SOCIETY OF ARTS, at 8.—Mechanical Road Carriages: W. Worby Beaumont.

TUESDAY, DECEMBER 10.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—The Recording of High Temperatures by Photographic Means: Prof. W. C. Roberts-Austen, C.B., F.R.S.—A New Form of Apparatus for Measuring the Densities of Photographic Plates: Chapman Jones.

ROYAL VICTORIA HALL, at 8.30.—The Rhine: Prof. H. G. Seeley, F.R.S

ROYAL ASIATIC SOCIETY, at 3.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, at 8.30.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion upon the Papers by Messrs. Arnold and Wrightson, on the Physical Properties of Iron and Steel.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—The Game of Teetotum, Queensland: R. Etheridge.—Notes on Australian Shields, more particularly the Drunmung: R. Etheridge.—Stone Cooking-Holes and Grooves for Stone-Grinding, used by the Australian Aborigines: R. H. Mathews.—The Burbung of the Wiradjuri Tribes: R. H. Mathews.—The Bora, or Initiation Ceremonies of the Kamilaroi, Part II.: R. H. Mathews.

WEDNESDAY, DECEMBER 11.

SOCIETY OF ARTS, at 8.—Adjourned Discussion on Mr. Cunynghame's Paper on Locomotive Carriages for Common Roads.

PHARMACEUTICAL SOCIETY, at 8.30.

THURSDAY, DECEMBER 12.

ROYAL SOCIETY, at 4.30.

LONDON INSTITUTION, at 6.—The New Far East: Arthur Diósy.

SOCIETY OF ANTIQUARIES, at 8.30.

MATHEMATICAL SOCIETY, at 8.—Note on the Convergency of Series: Dr. R. Bryant.—Sexdecimic Residuality of 2: Lieut.-Colonel Allan Cunningham, R.E.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Annual General Meeting.

FRIDAY, DECEMBER 13.

ROYAL ASTRONOMICAL SOCIETY, at 8.

MALACOLOGICAL SOCIETY, at 8.—The Culture of the Edible Oyster: Prof. Herdman, F.R.S.

CLINICAL SOCIETY, at 8.30.

PHYSICAL SOCIETY, at 5.—A Mechanical Device for performing the Temperature Corrections of Barometers: Dr. John Shield.—On the Existence of Earth-Air Electrical Currents: Prof. A. W. Rücker, F.R.S.

EPIDEMIOLOGICAL SOCIETY, at 8.

SATURDAY, DECEMBER 14.

ROYAL BOTANIC SOCIETY, at 3.45.

THE HISTORY OF MATHEMATICS.

Geschichte der Mathematik im Alterthum und Mittelalter. Vorlesungen von H. G. Zeuthen. Pp. viii. + 344. (Kopenhagen: Höst, 1896.)

A Primer of the History of Mathematics. By W. W. Rouse Ball. Pp. iv. + 146. (London: Macmillan and Co., 1895.)

THE first of these books is a translation, with some alterations and additions by the author, of a work originally published in Danish in 1893. Its aim is to supply students and teachers of mathematics with trustworthy information about such parts of the history of the subject as are really important for them to know; and, in particular, account has been taken of the fact that candidates for the Danish teachers' certificate are expected to show an acquaintance with the text of Euclid's Elements, as well as a general knowledge of the history of mathematical science. This plan has been effectively and judiciously carried out, and the result is a work of permanent value and interest, admirably suited for the class of readers for whom it is designed.

Dr. Zeuthen has very wisely adopted the course of tracing the lines of formal development along which the science of mathematics has progressed. This does not exclude the special consideration of the works of mathematicians of first-rate importance, while at the same time it brings clearly before us the different springs and rivulets, so to speak, which have converged into the broad and deep streams of modern geometry and analysis. Thus we are shown how the speculative and logical intellect of the Greeks built up a system, mainly geometrical, which at last seemed to become inert from the very perfection of form which it had attained; how the decimal notation of arithmetic and the elements of algebra, slowly evolved by the Indians, eventually made their way into Europe; and, finally, how mathematical science, preserved from extinction by the Arabs amid the ignorance and bigotry of the dark ages, woke up to new life in the thirteenth century, and grew slowly but steadily thenceforth, until the analytical method of Descartes and the invention of the infinitesimal calculus marked the beginning of a new era, the splendour of which has perhaps unduly obscured the achievements of all the ages which went before. We are all too apt to forget what we owe to our forgotten, unhonoured ancestors; and it is well that we should be now and then reminded that the exact science to which we are indebted for mos our "triumphs of civilisation," and which is ruly the finest product of the human mind, may be traced back to the dawn of history and the rude efforts of primitive man in the arts of counting and measuring.

But to return to Dr. Zeuthen's book. After a few introductory pages, devoted to *Vorgeschichte* and the Egyptians and Babylonians, we reach the longest and most interesting section of the work—that which treats of Greek mathematics. Here we have a clear, well-proportioned outline of the progress made from Thales to Diophantus, and of the scope and methods of Greek geometry and arithmetic, together with a sufficient analysis of the works of Archimedes, Apollonius, Diophantus, and more particularly Euclid. An interesting account is also given of the researches connected with the three famous problems of antiquity—namely, the trisection of an angle, the duplication of a cube, and the quadrature of a circle. (Archytas's construction for the second of these problems (pp. 84–5) is not very easy to follow: it would be an improvement to give a figure showing the circle traced out by the point Y.)

The amount of space given to the discussion of Euclid's Elements is justified by the importance of the subject. Dr. Zeuthen's criticisms of the definitions and postulates, and of Euclid's geometrical presuppositions, are very instructive; and his analysis of the contents of books v., vii.–xiii., ought to be of great service to students of the original text. There is only one point about which we would venture, with all respect, to differ from the author's conclusions. Dr. Zeuthen appears to regard the arithmetical books, and in particular book vii., as containing a theory of commensurable quantities; so that, for instance, the theory of proportion in book vii. is merely the substance of book v. adapted to commensurable ratios, and was composed because the general theory of proportion was still unfamiliar. This is not very plausible, *prima facie;* and it is, we think, disproved by the facts of the case.

The second definition of book vii. undoubtedly means "A number is an assemblage (πλῆθος, not μέγεθος) composed of units"; and if the word μονάς has the same meaning in the first definition that it has in the second (and this is almost necessarily the case), the true sense of the first definition will be "Any object whatever is a unit [or is regarded as a unit] when it is spoken of as *one*." If this be so, it is quite clear that we have to deal with a purely arithmetical theory; and there is nothing whatever in the form or matter of the seventh book inconsistent with this conclusion. It may be added that the definition of proportion in the seventh book is essentially distinct from that in the fifth; and that in some MSS., at any rate (*cf.* Gow's "History of Greek Mathematics," p. 74, note 3), numbers are represented by dots, and not by lines.

On the other hand, the tenth book does deal with quantities, and begins with a definition of commensurable quantities; a definition which, according to Dr. Zeuthen's theory, ought to have been given long before. It is quite possible that Euclid perceived the analogy between commensurable numbers and commensurable magnitudes; whether he realised the ratio of two commensurable quantities as a fraction in precisely the same wa as we ao s doubtful: it is almos certain that he ha no conception of surds as *numerical* quantities.

The Indians did not scruple to introduce irrational as well as negative numbers; by so doing, and by their invention of the decimal system of notation, they immensely extended the range of analysis, probably without knowing what they did. Except in the region of diophantine analysis, their particular discoveries are comparatively unimportant. However, Dr. Zeuthen does them full justice for all their researches; and we are glad, also, to see that he has a kindly word for the Arabs, who not only guarded the treasures of learning, but added something of their own to the store. Thus

we learn that Alkhojandi, about 1000 A.D., discovered that the equation $x^3 + y^3 = z^3$ does not admit of rational solutions.

A brief outline of the period 1200–1500 brings this excellent book to its conclusion. That it is the outcome of independent and careful research is evident; and the reader's appreciation of this fact is rather enhanced than otherwise by Dr. Zeuthen's graceful acknowledgment of his obligations to his predecessors in the same field, more particularly to Cantor and Tannery.

Mr. Ball's "Primer" is a work of a very different scope. Its object is "to give a popular account of the history of mathematics, including therein some notice of the lives and surroundings of those to whom its development is mainly due, as well as of their discoveries." It is expressly said that it is not intended for those to whom the subject is familiar. The plan adopted is to give a series of brief biographies in chronological order, interspersed with occasional paragraphs on particular periods. The necessary element of "human interest" is supplied by a number of anecdotes. Many of these are pertinent enough; others are certainly superfluous. Why should half a page be devoted to the unhappy matrimonial experiences of Kepler? or, again, what is the value of the information that Descartes in Paris was "modestly clad in green taffety?"

Still, the book is entertaining, and, although very sketchy, fulfils its purpose well enough until we come to the last section, which treats of recent mathematics. Here the difficulties of the subject, and the narrow limits of his plan, have been too much for the author. That this should be the case is not altogether surprising; but some of the faults of omission and commission are too serious to be passed over.

Thus in the paragraph on Cauchy, no mention is made of his work on the theory of numbers, or of his great memoir on waves. The statement that "the rule for finding the principal values of integrals was enunciated by him, and the calculus of residues was his invention," is much as if one should say "Newton discovered the binomial theorem and wrote the 'Principia.'" Worst of all, the account concludes with the remark: "In many of his memoirs the feverish haste with which they were thrown off is too visible, and several are marred by obscurity, repetition of old results, and blunders." Such criticism of a great genius is in questionable taste, and is apt to recoil on the person who makes it. It seems to us rather obscure to say (p. 132) that "in this theory the theta-functions are independent of the form of their space-boundaries"; and that Eisenstein "considered the theorems relating to the possibility of representing a number as a sum of squares, and showed that the general theorem was limited to eight squares." Will not the general reader infer from this that no number is the sum of more than eight squares?

Then as to inadvertent errors (it would be unkind to call them blunders): (1) it is not true that "the only regular polygons which can be constructed by elementary geometry are those of which the number of sides is $2^m(2^n + 1)$, where m and n are integers and $2^n + 1$ is a prime"; even Euclid could construct a regular quindecagon; (2) the theory of ternary quadratic forms is not due to Eisenstein; (3) Eisenstein did not give a rule for distinguishing whether a given series represents an algebraical or a transcendental function (see Heine's "Kugelfunctionen," 2nd edition, i. p. 50); (4) Abel did not prove that it is impossible to solve a quintic equation by means of radicals, but the quite different proposition that a root of the *general* quintic cannot be expressed in terms of its coefficients by means of radicals.

Finally, the omission of all notice of Galois is entirely inexplicable. The pathetic story of his death appeals to universal sympathy, and might even draw a tear from the hardened general reader; while the influence of his work upon recent analysis is, perhaps, second only to that of Riemann.

Fault-finding is not pleasant, and is apt to bulk too largely in a review. Mr. Ball's readers may not be impressed by the fact that Cayley "introduced the so-called 'absolute,'" and they may be inclined to think that "homaloidal hyper-space" is a somewhat technical expression; but they will find plenty of amusement in the "Primer," and a good deal of instructive reading; while, for reasons which are different, but each sufficient, the occasional *lapsus calami* will do neither the instructed nor the uninstructed reader any harm. G. B. M.

THE SPIDERS OF BURMA.

Descriptive Catalogue of the Spiders of Burma, based upon the Collection made by Eugene W. Oates, and preserved in the British Museum. By Dr. T. Thorell (London: printed by order of the Trustees, 1895.)

DURING his residence in British Burma, in the capacity of civil engineer, Mr. E. W. Oates availed himself of the rare opportunities of travelling, afforded by his official duties, to investigate certain portions of the fauna of the country, choosing as objects of special study such diverse groups as Scorpions, Whip-Scorpions, and Spiders; Centipedes and Millipedes; and Birds. It was, we believe, primarily his intention to work out all his collections himself upon his return to England on furlough. In fact, while still in the East he published, in the *Journal of the Asiatic Society of Bengal*, descriptions of his new species of Whip-Scorpions (*Thelyphonus*), and shortly after his arrival, his paper upon the Indian and Burmese species of Scorpions of the genus *Isometrus* appeared in the *Journal of the Bombay Natural History Society*. But further than this, his studies in the invertebrate portion of his material did not go; and realising the impossibility of grappling in the space of time at his disposal with the vast number of species of spiders and myriapods that he had procured, he generously presented these in their entirety to the Trustees of the British Museum, and devoted his energies to the study of the Birds of British India and Burma, of which he had already acquired considerable knowledge. In the course of the next few years, the Centipedes and Millipedes were determined and reported upon in a series of memoirs that appeared in the *Annali del Museo Civico di Genova*. The spiders, however, were, at Mr. Oates's request, submitted for examination to Dr. T. Thorell, who had already made himself an authority upon Burmese Arachnida, in connection with the study of the material of this group amassed under the auspices of the Marchese G. Doria by that practised

collector, Sig. L. Fea. But although the Italians, n the persons of Sigg. Fea and Comotto, had had the first bite at the Burmese Arachnid fauna, the careful sorting and examination of Mr. Oates's collection soon showed that this gentleman had more than doubled the number of known Burmese spiders. For whereas only 175 species had been previously recorded, the total number now amounts to no less than 381. Mr. Oates's collection thus contains 206 species that are new to Burma, and of these 153 appear to be new also to science. It comprises, moreover, either the males or females of many species of which only one sex had been hitherto described.

The secret of Mr. Oates's success as a collector of spiders is to be attributed partly, of course, to his paying special attention to them, but largely to his ingenious mode of attracting them. He tells us that—

"The greater part of the collection was made at Tharrawaddy [a station about seventy miles north of Rangoon], where I had a large garden, and a portion of it was specially prepared for the attraction of spiders, which came to it in large numbers. I put in plants of those species which my experience told me were specially affected by spiders, and by this means I was able to observe very many species in a small compass. By carefully watching the females for some weeks, I generally contrived to secure the males in such a manner as to render their identification with their respective females certain. In addition to the garden, there were large forests not far from my house. I collected at all seasons of the year, but I found the rains, from May to October, most productive. I was greatly assisted by my wife, who soon overcame her natural repugnance to spiders, and handled them freely."

With such exceptional opportunities of observation at his command, it is a matter for regret that Mr. Oates made so few notes upon the bionomics of the species he collected. For it is no exaggeration to say that if records had been kept in the case of each species of its habitat, and method of courtship and of the structure of its cocoon and snare, the value and interest of the collection would have been greatly enhanced. In the case, however, of *Herennia multipuncta*, an Epeiroid allied to *Nephila* and *Argiope*, and widely distributed in the Oriental region, Mr. Oates made the following observation :

"Makes a web about three feet long on a smooth tree-trunk, width one-third or one-fourth of girth of tree. All the lines are vertical or horizontal, forming a perfect rope-ladder. The web follows the convexity of the trunk, and is everywhere about half-inch from it. Verticals about one inch apart, horizontals about quarter of an inch apart."

With justice does Thorell term this : "annotatiunculam magni momenti," and add "rete formæ adhuc plane ignotæ igitur facit, *Herennia multipuncta*"! Curiously enough, however, M. Simon asserts that this same species, as observed by him in Ceylon, makes a snare, as indeed one would have supposed to be the case, of the ordinary orbicular type. We are consequently at a loss to know quite what value is to be attached to Mr. Oates's statement.

Turning to the spiders themselves, perhaps the only one amongst the new genera and species that calls for special mention is the remarkable new form *Prolochus longiceps*, which although presenting many points of similarity to the familiar epeiroid, *Meta segmentata*, differs from all the orb-spinners that have been hitherto described, in having only six large eyes and the cephalic region of the carapace very high and long. In this last respect it somewhat resembles the spider named *Archæa*, which was described by Koch and Berendt from the Oligocene amber beds of the Baltic. Thorell consequently refers it, although provisionally, to the Archæidæ (written by him Archæoidæ), and classes the family with the Retitelariæ, although for what reason does not appear. Probably the best way of disposing of the difficulty would have been the establishment of a new family for the reception of this anomalous spider.

So far as the rest of the genera and species are concerned, there appears to be nothing particularly remarkable in the collection, excepting only the new genus of Attidæ named *Ligdus*, which in its flattened form and the position of its enlarged first pair of legs presents a strongish superficial resemblance to one of the False-Scorpions (*Pseudoscorpiones*).

Most persons who glance through this book will probably be surprised and disappointed to find that the 400 pages of letterpress are relieved by no illustrations ; but those who are familiar with the rest of Dr. Thorell's works, will know what they have to expect on this head. The lack of figures, however, is made good, as far indeed as is possible, by the fulness of the specific descriptions, which often run to more than two pages of print. Some, perhaps, may be disposed to think these descriptions are unnecessarily long ; but on such a point, Dr. Thorell's opinion is probably of greater value than that of any other person : and it is only fair to him to mention that, in addition to the description, a briefer diagnosis of each species is subjoined, so that the attempt to identify a species does not necessarily entail a large amount of fruitless reading. We greatly regret, however, the author's stern adherence to the practice of not compiling synopses of his species. For there is nothing like a carefully compiled synoptical table for bringing home to an author and his readers the essential characteristics of the species being dealt with.

In the introduction Dr. Thorell takes the opportunity of explaining his opinions upon some of the many vexed questions connected with zoological nomenclature. But although we find it impossible to agree with all that he holds, the views of such an accomplished linguist are worthy of the greatest attention, especially where questions of philology are concerned ; and we earnestly commend them to the notice of those who in the construction and adoption of zoological names wantonly violate every canon of etymology, until "it seems as if neither common sense nor the dignity of science can claim any rights against the whims, carelessness, or ignorance of certain authors." Speaking, for instance, of the adoption without alteration of ungrammatically formed specific names, Dr. Thorell says :

"It is an essential rule in the Linnæan system that the scientific names of plants and animals shall be in *Latin*, at least as to their form. Now as a great number of specific names consist of the genitive of personal proper names, that genitive should, when possible, be formed in analogy with the genitive of Latin names or other words of a similar form. The genitive, for instance, of Caligula,

Livius, and Catullus being *Caligulæ*, *Livii*, and *Catulli*, I cannot accept such specific names as *Doriai*, *Retziusi*, *Catulloi*, but consider that they should be corrected to *Doriæ*, *Retzii*, *Catulli*."

With regard to genera, Dr. Thorell considers that such terms as *Scorpio* and *Aranea*, cannot be used in a generic sense, because in the plural form they are applied respectively to the orders of Scorpions and Spiders. This view, however, is, we venture to think, untenable. For the terms were used by Linnæus generically before they were used ordinally; therefore, if it be considered necessary to change either the generic or the ordinal name, it is surely the latter that should be abolished. Moreover, in the interests of nomenclature it is more important that the generic name should be stable than the other. And curiously enough, Dr. Thorell, with apparent inconsistency, seems to take this view of the case when there is any clashing between the name of a family and of one of its genera. For he always, and we believe correctly, forms he family-names with the termination—oidæ, such as Lycosoidæ instead of the more usually accepted Lycosidæ. But he affirms that if there be a genus termed *Lycosoides* contained in the family Lycosoidæ, the latter name must be altered, and a new one constructed from some other genus, *e.g.* *Trochosoidæ*, be adopted. The practical application of this view has led him to abandon such ong-established family-names as Epeiroidæ, Thomisoidæ, Attoidæ ; but if it were to be consistently and universally adopted, it is clear that all the family-names now in vogue, and every successive substitute, might have to be changed and again changed *ad infinitum*.

One other point deserving of notice is Dr. Thorell's opinion that the priority of *species*-names should be reckoned from 1751, when Linnæus, in his "Philosophia Botanica," proposed and gave rules for his binomial nomenclature. Most zoologists now refer back to 1758, the date of the publication of the tenth edition of the "Systema." But Linnæus's disciple Clerck published in 1757 his classical work "Aranei Suececi," in which he describes and gives good coloured figures of about sixty species of Swedish spiders, with binomial names according to Linnæus's system, and no arachnologist can admit that these names ought to be rejected simply because they were published *before* the tenth or twelfth edition of the "Systema." Such questions as these, however, we may perhaps leave with safety and confidence in the hands of the two recently appointed bibliographical committees, from which so much is expected.

R. I. P.

COLOUR VISION.

Colour Vision: being the Tyndall Lectures delivered in 1894 *at the Royal Institution.* By W. de W. Abney, C.B., D.C.L., F.R.S. (late R.E.) Pp. ix. + 231, 8vo. (London: Sampson Low, Marston, and Co., 1895.)

CAPTAIN ABNEY has long been known as the authority upon the scientific measurement of colour, and his researches have naturally involved a continual attention to the problems of colour-vision. This, too, he has made the subject of measurement in numerous ways, and in observations extending over many years. The results of his work in the domain of colour-vision were systematically expounded by him in the "Tyndall Lectures" of 1894, and have now been recast in their present form. The volume, which is sumptuously printed in double-leaded type, is illustrated not only by numerous cuts and process-blocks, but by an excellent chromolithographic spectrum chart of the typical cases of colour-vision. It is worthy of the reputation of the President of the Physical Society, and constitutes a distinct addition to the literature of physiological optics.

The work, as published, is now arranged in chapters without reference to the original disposition of the subject-matter when delivered in the form of lectures ; and a very large portion of the book is devoted to the various cases of colour-blindness, both congenital and acquired, including the species of amblyopia due to excessive use of tobacco. In the opening chapter, which deals with the anatomy and physiology of the eye, the fascinating theory of the "visual purple" is mentioned, only to be at once dismissed as incompatible with the fact that that part of the retina which is most sensitive both to light and colour, the forea centralis, is destitute of the structures which alone contain the substance which possesses the purple reaction. The second chapter deals with the wave-lengths that correspond to the several colours of the spectrum, and with the apparatus devised by the author for producing any desired mixtures of spectrum tints for the purpose of colour-matching. The physical proofs that green is a primary colour because it cannot be made up by mixing any two other colours, and that yellow is not a primary because a yellow can be made by a mixture of two others, are given very clearly. On p. 24 the author remarks that "we are all familiar with the fact that there are three primary colours," whereas the fact is not that the colours are primary, but that the sensations are primary ; and he assumes, without any proof save that of indirect inference, that these primary sensations are three in number. Indeed, in another passage the admission seems to be made that the sensations which are primary are four in number.

Quoting from Prof. Michael Foster's epitome of Hering's theory of colour-vision, the author gives the following statement.

"The sensations caused by different kinds of light, or by the absence of light, which thus appear to us quite distinct, and which we may speak of as 'native' or 'fundamental' sensations, are white, black, red, yellow, green, blue. Each of these seems to us to have nothing in common with any of the others, whereas in all other colours we can recognise a mixture of two or more of these. . . . Hering's theory attempts to reconcile, in some such way as follows, the various facts of colour vision with the supposition that we possess these six fundamental sensations. The six sensations readily fall into three pairs, the members of each pair having analogous relations to the other. In each pair the one colour is complementary to the other, white to black, red to green, and yellow to blue."

Commenting on this theory as so stated, Captain Abney says that it should be described as "tetra chromic" (should it not be chromatic ?) rather than "tri-chromic," for as far as "colour" is concerned, the black-white sensation must be excluded But, surely

there is much more to criticise in so crude a presentation of the case. Is not brown just as truly a "native" or "fundamental" sensation as green or blue? Without an education it would be impossible to pronounce it to be a mixture of any other two of the "native" sensations. The writer would go further, and include amongst native sensations that of purple, the pure full purple so rarely occurring in nature. To him, indeed, violet suggests a mixture of blue and purple, while crimson suggests a mixture of the sensations of purple and red. Further, it is not strictly true of the six supposed native sensations connoted by the six names given above, that they are in each pair complementary to each other. The true complementary to yellow is violet, not blue; the true complementary to blue is orange, not yellow. The true complementary to red is not green, but blue-green or peacock; and the true complementary to green (full green) is not red, but a crimson tending toward purple.

In other parts of the work, Hering's theory is compared with Young's theory; and a really decisive point in favour of the latter is made on p. 136, where it is shown, from the experiments made on the gradual extinction of luminosity down to the tints that persist last when all others have become invisible, that the finality of disappearance in the case of persons of monochromatic vision is inexplicable on Hering's physiological assumptions.

Many other points in the work show acute observation. The remark that no colour-match can be accepted unless we know the portion of the retina used in the operation is an instance, for the match will be different if the portion used is the macula lutea instead of a larger area of retinal surface; while, again, the colour-vision at 10° obliquity differs even in the normal eye from that of the forea centralis. The instructions how to pick out from the spectrum tints those which excite sensations that are primary, on p. 93, though not too clearly expressed, are readily understood; and of great value to future workers. The experiment of producing the neutral or a-chromatic sensation of light by means of a glow-lamp under a shade of blotting-paper, is both novel and neat.

Unfortunately the author occasionally uses words and phrases in a special or technical sense of his own devising, and which he does not define. It is left to the reader to discover, if he can, what the meaning is. For example, on p. 112, the words "the extinction" are used not to mean the disappearance of the light, but to mean, apparently, the percentage degree to which the light has to be reduced in order to be practically imperceptible. Unless one finds out by some sort of intuition that the word is being used in this unusual sense, one is puzzled to read three pages further on that "if we multiply the extinction by the luminosity, we shall get what we want.' Indeed, the word "luminosity," used so often throughout the work, needs to be better defined; and it ought to be used, when defined, only in one sense. There are several passages in which the word occurs, where it is not evident whether the term "luminosity" refers to the number of candles per unit area (the sense in which one would speak of the intrinsic or specific luminosity of the crater of the electric arc, or of the flame of a lamp), or whether it refers to the illumination of a surface in terms of the illumination due to a standard light at a standard distance, or, lastly, whether it refers to the apparent luminosity as viewed by a person of possibly abnorma vision. Yet at the bottom of p. 115 we are told that the author has taken "the luminosity of the yellow light near D [in a particular experiment] as one amyl acetate lamp." Taken literally and grammatically, luminosity here means simply "one lamp" of a kind that is known to be equal to about 0·87 of a standard candle. The plaintive remark on p. 181, that the word "brightness" is misleading to some people who are uneducated, is a curious commentary on the use of a word that will mislead some who are not uneducated. In a certain "criterion by the luminosity method" (p. 182), red is placed beside white, and the subject is asked to say which he considers the *darker*. This is to avoid asking him (lest it should be misleading) which he considers the brighter. Does the word luminosity as here used mean anything more than brightness? Again, on p. 110 we read: "The spectrum was of such a brilliance that the intensity of the square patch . . . of the orange light (D) was exactly that of an amyl-acetate lamp, placed at one-foot distance from the receiving screen. Knowing this, the actual luminosity of all other rays of the spectrum can be derived from the curve of luminosity." In this passage, has not the word "intensity" precisely the same meaning as "luminosity"? And does not the word "brilliance" again mean the same thing? Would not the passage be exactly as clear if the word "brightness" had been used instead of the three different words in the places where they occur?

The most valuable part of the work is that which relates to colour-blindness, where, for the first time, there are given charts showing the degree of *apparent* luminosity (the qualifying adjective is the reviewer's) in different parts of the spectrum to persons having one or other variety of colour-blindness. One case, mentioned on p. 85, is of exceptional interest. This is the case of a person who, though he sees each of the three fundamental colours quite correctly, red as red, green as green, violet as violet, is relatively less sensitive to green than other persons of normal vision. "He is defective in the green sensation, although it is present to a large extent." Here is a person who certainly would be quite capable of doing duty as an engine-driver or as a seaman, perfectly able to distinguish green lights from red, but who yet would be condemned, if tested by the much over-rated method of Holmgren, as being colour-blind. Indeed, the least satisfactory part of Captain Abney's book is that wherein, in the face of this very case in which Holmgren's wool tests would unjustly condemn a man, he describes and praises the Holmgren method of testing colour-vision. There is not one word of warning as to its uselessness in such cases, or as to its misemployment by practitioners devoid of any training in the optical laboratory. Captain Abney says that he "is glad to say" that the Holmgren system has been adopted by the Board of Trade and by most of the railway companies in the United Kingdom. The pity is, that no one explains to those who have to use it how easily the coloured wool test may be (and actually is) misused, and how in certain cases, like that cited, its indications may inflict a serious injustice.

S. P. T.

SELBORNE ILLUSTRATED.

Natural History of Selborne, and Observations on Nature. By Gilbert White. With the Text and New Letters of the Buckland Edition. Introduction by John Burroughs. Illustrations by Clifton Johnson. Pp. xxiii., vi., 208, 231. (London and New York: Macmillan and Co., 1895.)

YET another edition of White's "Selborne" has been issued by Messrs. Macmillan; and there are really some points about it which fully justify its appearance. It is in some degree an *édition de luxe*, being printed in beautifully clear type on thick glazed paper, and arranged in two neatly-proportioned volumes, which are fully illustrated.

The text is that of the Buckland edition. There are no editor's notes to speak of, and such of the "Observations," which it was thought desirable to include, have been inserted at the end of those letters to the subject of which they have reference. We have had many annotated editions, both good and bad, and probably no new one would tell us anything more concerning the subjects White wrote of in, or serve to elucidate further, the famous letters. Recent research has brought to light additional materials for a biographical sketch of White; but apart from this, we are inclined to dread the overdoing of the annotating —for overdone it assuredly was in some editions.

In his Introduction, Mr. Burroughs considers the reason of the longevity of this "cockle-shell of a book." He concludes that it is like plain food, neither exciting nor cloying; that, written by a born countryman, it has a home flavour about it. We are attracted by its sound style, and that precious sense of reality breathed in his sentences; by White's infinite curiosity, and his caution in making sure of his facts. But Mr. Burroughs is not quite just in one passage; it was *honey* dew, and not *heavy* dew, which White thought proceeded from the effluvia of flowers, although he was equally wrong in his supposition of the origin of that substance. Nor do we think that White succeeded finally in persuading himself that swallows in their ability to hybernate in a torpid state, stood on the same footing with bats and "turtles." As late as 1784 he had gone no further than considering the hybernation of house-martins probable. White received many facts relating to migration from his brother at Gibraltar, and in one letter we find him arguing in favour of migration in general with Daines Barrington, who was "no great friend to migration."

It seems to us that in this Introduction, one great charm of the "Natural History of Selborne" has been lost sight of.

White lived in England's golden age of leisurely prosperity, and it is just this air of leisureliness and freedom from any signs of hurry and worry, which gives his book its great charm, as its accuracy gives it its great value. In those days the man of small property who lived in a retired part of the country had practically no demands on his time, beyond such as he chose to make for himself in the direction of his garden, his live-stock, and his house. Society, as we understand it now, must have been unknown at that time to those who did not go to town. It was not necessary for White to pay calls, or to go to functions. A little "neighbouring" in the village and its immediate vicinity at convenient times, and some visits exchanged once or twice a year with well-tried friends, fulfilled all demands of that kind, although, as we see from the letters to the Barkers, White was fond of filling his house with friends and relations. There were in those days no stirring "movements" on foot, for the edification of men and women in the abstract, to claim his philanthropic attention, though we may be sure the needy of Selborne were not forgotten. To be well-read meant that a man might read the classics and a few favourite authors at leisure, instead of struggling with the stream of new books, with its ever-gathering strength and volume. White had not to acquire a smattering of a dozen sciences and a superficial idea of art, or to assimilate eight pages of a daily newspaper in order to fit himself to meet his enemy intelligently in the gate. At Selborne he had perfect leisure, and could bring an intellect, unstrained by his leisurely studies, to bear in unhurried observation on the comparatively limited outdoor objects of his quiet parish. Doubtless he had trained his observing eye and mind, as so many have trained them, in his sportsman days; and the habit of keeping a careful diary fostered accuracy in a mind naturally exact. It was, we imagine, his love of Selborne which prompted the production of his book; for if he observed much elsewhere, he did not note down his observations. Had he done so, we should surely have found in his letters more frequent references to the period of his residence at Oxford, then comparatively a leisurely place itself.

Undoubtedly the chief attraction in the present edition is the illustrations. For the first time we have a set which give us an idea of what Selborne village and neighbourhood are like. It is true that it is Selborne a century after White's death, which is represented, but we imagine that there must be much that is but little altered. We should have valued a few contemporary views very dearly. As we write, we have been turning over the leaves of another copy of the "Natural History," "a new edition with engravings," issued in 1822, and edited by John White, of Fleet Street. But the only illustration of scenery it contains is a view of the "grotesque building constructed by a young gentleman who used on occasion to appear in the character of an hermit." Some years ago it was our pleasant fortune to meet a relative and namesake of the author, who told us that the original of this sketch was still in existence. If there are any more eighteenth-century Selborne landscape pictures available, how admirably they would have embellished this edition! The illustrations in the two volumes, the subject of this notice—chiefly reproductions from photographs—will be heartily welcomed by those who love the book. Those who have made their pilgrimage will value them as a souvenir of their visit, while those who cannot go to Selborne will now have its quiet scenery brought to them. Though many changes have come to Selborne in the last hundred years, yet there must be some things left very much as White saw them. His house and his garden do not appeal much to us in the pictures, nor does the interior of the church, which seems to have suffered restoration, but we are very glad of his old sun-dial. Rick-building is a thing likely to be carried out conservatively in the local fashion,

while thatching is a rural fine-art handed down mostly from father to son. So it is probable that the corn-rick in Norton farmyard (p. 54) is similar in make and shape to that, for instance, under the thatch of which "were assembled near an hundred" harvest mice; although most probably in White's time all the ricks were erected on "staddles." The rick in the illustration is unlike the oblong square ones usual in some districts, and the round ones prevailing in others; it is square, and has the corners neatly rounded. There are some excellent views of the irregularly shaped thatched cottages, which are probably but little altered, and possibly the same may be said of the substantially-built houses seen when looking across the Plestor. The Plestor, the famous wooded "Hanger," and the Long Lythe—a favourite walk of White's—are quite familiar scenes in the mind's eye of White's readers. Views of Wolmer Pond and Wolmer Forest, once the haunt of wild red deer and black game, and where White found teal breeding, which he looked upon as "a great stroke in natural history," are very suitable illustrations, and we are charmed to have a picture of one of the "little round ponds" on the sheep-downs, which never dried up. But why insert a view of Stonehenge? White certainly mentions it; but so he does Oxford, Calabria, and other places which have nothing particular to do with Selborne. The figure of the "Rook-starver" (Rook-scarer) suggests the question whether this was a name of White's day. Most of these curious local names are old; but the Hampshire villagers must have differed from those of the Midlands, for instance, who invariably call rooks crows, and talk about "Crow-keeping." One of the prettiest views is that of an old cottage in the Lythe backed with clumps of hanging wood, and there is a very nice picture of a rookery.

There are a good many illustrations of birds, which in some, if not all, cases seem to have been reproduced from photographs of stuffed specimens. With hardly an exception they are quite as unsatisfactory as illustrations of this kind usually are, and some of them are exceptionally bad.

In the present edition the arrangement of the letters to Pennant and Daines Barrington in two separately numbered series is departed from, the whole being fused and arranged chronologically; this, especially to those used to the other style, makes the want of an index more felt. The second volume concludes with the new letters to members of the Barker family, and the Calendar.

O. V. APLIN.

PLANT PHYSIOLOGY.

Das Pflanzenphysiologische Prakticum. Von Dr. W. Detmer. Mit 184 abbildungen, zweite völlig neu bearbeitete Auflage. (Jena: Fischer, 1895.)

IN the new edition of this standard book, the general arrangement of the first edition has been for the most part adhered to, but in other respects great changes have been made. Nearly every section has been re-written and enlarged, a large number of new experiments have been added, and in every case great care has been taken to give full details for carrying out the observations described. Among the sections added, the following may be mentioned: on the relation of the stomata to assimilation; an account of experiments on species of the natural family Papilionaceæ, illustrating their relation to the bacteria normally found in their roots; on nitrification, including an experiment on nitromonas, one of the remarkable organisms capable, without the action of light, of forming organic substances from inorganic materials. Another addition is the section on mykorhiza. In dealing with the intercellular system of plants, it is strange that Prof. Detmer still quotes the intercellular space, which accompanies the bundles of *Zea Mays*, as an example of a passage which is of importance in the exchange of gases and the aëration of the tissues; while it is almost certain that this passage is chiefly serviceable in conducting water in the plant. The sections dealing with transpiration have been materially enlarged and improved, although it is difficult to see how the author could be inclined towards Westermaiers and Godlewski's theories after Strasburger had so completely answered them. It is to be noted that, in an appendix, Prof. Detmer appears to accept the theory which regards the upward motion of the sap as due to the tension set up by the evaporation taking place in the leaves, and transmitted downwards through the water-columns in the tracheidal system. He, however, apparently by an oversight, attributes this theory to Prof. Askenasy, who himself, in the paper describing the theory, acknowledges the priority of its English authors.

In treating of the development of heat and phosphorescence by plants, much new matter has been added. The raising of the temperature of flowers above that of their surroundings, is doubtless often an attraction for their insect visitors; and it appears strange that phosphorescence should not be made useful in the same way, and that while many of the lower plants exhibit this phenomenon, yet in the flowering plants authentic instances of phosphorescence under normal conditions seem to be unknown. *À priori* we might consider that phosphorescing flowers would be very efficient in attracting night-flying insects for purposes of pollination, especially as this method of arresting attention is shown to be successful by several instances in the animal kingdom.

The portion of the book allotted to the movements of plants in response to stimuli, is clearly written, and contains accounts of much recent research in this field of plant physiology. Illustrating this subject, there is plenty of material for beautiful and striking experiments; perhaps one of the prettiest, described by the author, is an experiment on the chemotropism of the pollen-tube. A leaf of Tradescantia is injected with a sugar solution, and afterwards quickly washed in water and dried on the surface. On the under surface, which is rich in stomata, a number of pollen-grains are scattered, and the leaf thus treated is kept in a damp chamber. After a certain time it may be observed that the tubes of the germinating pollen-grains are each directed towards some one of the stomata, showing that the sugar solution in the stoma, and the intercellular spaces connected therewith, induces a chemotropic movement in the pollen-tube.

In its new form the book is certainly one of the most complete, if not the most complete, text-book of plant physiology. For although it is much smaller than Sachs'

classical "Lectures," yet it is so concise, that there is room in it to describe as many or more experiments than in the latter book; and it contains a great amount of recent work, which is naturally not to be found in the older text-book. The conciseness has, of course, its disadvantages, for in consequence of it the book is not so readable, nor is there space for the same philosophical treatment of the subject which is characteristic of the work of Sachs. Much, however, is done to lessen these necessary drawbacks by the clearness of the arrangement and the descriptions, and references to the original papers are in most cases given, so that the reader is presented with much of the literature on each subject. From these references the names of English authors are almost completely absent; this is in part due to the fact that, unfortunately, so few of our countrymen occupy themselves with plant physiology, and in part to the fact that, even when such work is to hand, the author often fails to allude to it.

Finally, the usefulness of the book is increased by a very complete index; and we are glad to learn that an English edition is in preparation. H. H. D.

OUR BOOK SHELF.

Science and Art Drawing: Complete Geometrical Course. By J. Humphrey Spanton, Instructor in Drawing, H.M.S. *Britannia.* Pp. 582, and 689 figures. (London: Macmillan and Co., 1895.)

THIS is a somewhat bulky but handsome well-printed volume, the title of which is a little unfortunate; it should, however, prove useful to students preparing for such examinations as those of the Science and Art Department, for the Army, or for Cooper's Hill. The author takes as a basis the South Kensington syllabus, and, by sundry additions, covers nearly the whole ground necessary for other examinations. The book is a trifle paradoxical, for while in the solid geometry information abounds, in the plane geometry the opposite is the case, and generally anything approaching to an explanation of the principles underlying the constructions has apparently been eliminated. This, we think, is a matter for regret, as a much larger sphere of usefulness would be obtained by a few judicious explanations, or by an occasional reference to Euclid; indeed, a step further might well be taken, and the equations of curves be given. The student would thus be familiarised with mathematical formulas, and by a little instruction would be enabled to follow the *rationale* of the construction instead of simply learning it by heart; for instance, the equation, $r = a + b \operatorname{cosec} \theta$, of the conchoid of Nicomedes (p. 183), shows at once the reason for the given construction being adopted. Such additions need not necessarily make the book more bulky, as the drawings on pp. 31–34, 60, 61, 78–80, and 164 might well be omitted.

The figures, which must of necessity form a distinctive feature in a work of this nature, are good throughout; those for the plane geometry, however, suffer by comparison with those of the remainder of the book, as the lettering of the former is not by any means neat; also, some of the diagrams illustrating horizontal projection are too small. For exhibiting the conic sections to junior students, the author hits on the happy method of cutting off, from the light of a candle, a cone of rays by means of a circular hole cut in a sheet of cardboard, and then by inclining another piece of cardboard across the cone the various conics are produced in shadow; later on, the conics are again discussed in an instructive manner as the sections of a cone. The author is not always fortunate in his definitions, and ambiguities occasionally occur; for instance, the spheroid (p. 13) is defined as "resembling the sphere in shape, but all its sections are not circles." Again with the conchoid (p. 183), we are told that "it has the *peculiar* property of always approaching nearer a straight line as it is produced, but would never meet it." From this it would almost appear that an asymptote occurred with the conchoid only, as it is never mentioned elsewhere, not even in connection with the hyperbola.

In the solid geometry the interest of the student is first excited with the plan and elevation of the simple solids; then a good chapter on spheres and spherical triangles is incongruously wedged in between this and the following chapters on points, traces of lines and planes, intersection of solids, &c.; the author faithfully following the South Kensington syllabus (omitting, however, any reference to perspective), and finally closes with elementary graphic statics, in which, by the way, a slight error has occurred in Fig. 331, the component (q) being shown in the wrong direction. The pages are remarkably free from error, and the book will no doubt fulfil a want felt by many for a practically complete course.

The Discovery of the Anti-Toxin of Snake-Poison.

I DESIRE, without offering any comments on the facts, to bring under the notice of your readers the following simple statement.

In the *Annales de l'Institut Pasteur*, May 1894, Dr. Calmette described in full detail his researches on snake-poison, and demonstrated that not only can animals be rendered resistent to cobra (and other snake) poison by the injection into them of graduated doses of the poison (so that rabbits were rendered tolerant of sixty times the lethal dose), but that the serum of such immunised rabbits is found to contain a powerful anti-toxin which can be used successfully as an antidote to snake-poison. In April 1895, in the same *Annales*, Dr. Calmette described the results of a year's further work on this subject, giving the most important facts as to the antidotal action of snake anti-toxin in regard to poisons allied to snake-poison, and of other anti-toxins in regard to snake-poison.

On both occasions Dr. Calmette formulated his discoveries in such a way as to render them applicable to the treatment of snake-bite in man.

On June 3, 1895, Prof. Thomas R. Fraser, of the University of Edinburgh, read to the Royal Society of Edinburgh a paper (subsequently printed in the *Proceedings* of that Society) "on the rendering of animals immune against the venom of the cobra and other serpents; and on the antidotal properties of the blood-serum of the immunised animals."

In this paper, read more than a year after Calmette's first paper above cited was published, Prof. Fraser has refrained from any textual reference to Calmette's published work. His only mention of Calmette is as follows: "Within the last few months, Phisalix and Bertrand have obtained experimental indications of the antidotal power of the blood-serum of animals immunised, but only to a low degree, against the venom of vipers; whilst Calmette, working in the Pasteur Institute of Paris, after several unsuccessful endeavours had led him to express the opinion that immunity against snake-venom could not be produced, afterwards succeeded in obtaining evidence of its production, and of the power of the blood-serum to counteract the effects of venom."

The medical journals of Great Britain have represented Prof. Fraser as the discoverer of the anti-toxin of snake-poison. Two distinguished Edinburgh biologists—Prof. Geddes and Dr. Arthur Thomson—writing on Pasteur in the *Contemporary Review*, have put forward Prof. Fraser as one who has made an important life-saving discovery which is the latest fruit of Pasteur's fertile conceptions.

As a matter of fact, any one who will take the trouble to read Dr. Calmette's papers and Prof. Fraser's, will find that the sole credit of discovery in this matter rests with Dr. Calmette, who worked under the direction and with the suggestions of Dr. Roux.

It would be interesting to know whether the *Annales de l'Institut Pasteur* are accessible to Prof. Fraser, and whether he thinks that his vague reference to Calmette's detailed researches, and his designation of the interval between May 1894 and June 1895, as "a few months," are calculated to give to the British public a fair notion of the merit in this matter of his French colleague.

E. RAY LANKESTER.

Oxford, November 28.

The Maerjelen Lake.

A CORRESPONDENCE which I was recently the innocent cause of initiating in the *Standard*, revealed a very remarkable conflict of evidence touching the question of how often and to what extent the Maerjelen Lake[1] has of late years emptied itself. As I pointed out, the rare phenomenon of a total discharge of the lower basin through the Aletsch glacier recurred last September; whilst in the great majority of cases, a pool more or less deep is left in that basin, and the upper, more shallow basin is never quite empty.

Considering the grandeur of the emptying of the lake as an Alpine phenomenon, it might reasonably be expected that those who are fortunate enough to witness it, would take the trouble to note the dates and facts accurately. Such, however, is rarely the case, for many eye-witnesses are so led away by their enthusiasm at the time, and so deceived by their memory afterwards, that their evidence is often flatly contradictory, and hence of little or no value. This is strikingly illustrated by the public correspondence referred to, as well as by private letters and other information I have received since.

It would lead too far to enumerate all the vague and contradictory statements, both as regards dates and facts. Suffice it to mention that, while some eye-witnesses infer a total emptying of the lake simply from having seen a rush of water along the surface of the Aletsch glacier, others draw the same inference from the fact that they saw the lake empty. But neither of these inferences affords proof of a total discharge; for in the first case, only a partial discharge may have taken place, such as last occurred in September 1894, and in the second case, the lake, unless it was seen full the day or a few days before, may have been partially or completely empty for months. A partial emptying is of frequent occurrence; but the only true test of a total discharge, as authentically recorded, *e.g.* in 1864, 1878, 1887, and 1895, is the exposure of the glacier wall to its full depth of at least 150 feet immediately after the event. Some years ago, Prof. F. A. Forel gave a list of the recorded discharges (without special reference to partial or total discharges) up to 1890);[2] but even that list cannot, and, I believe, does not lay claim to completeness and strict accuracy.

The occurrence of September this year is of peculiar interest, because it shows that, notwithstanding the recently completed artificial overflow tunnel to the Viesch glacier, the Maerjelen Lake prefers its old outlet through the Aletsch glacier.

C. S. DU RICHE PRELLER.

The Former Northward Extension of the Antarctic Continent.

I SHOULD not presume to draw the attention of your readers to this much-discussed topic without having a new fact to contribute. The opportunity of loading still further the already overweighted scale which now dips so deeply in favour of the notion of a former northward extension of the Antarctic continent, has been afforded me by the kindness of Prof. Parker, F.R.S., of Otago, New Zealand. He has forwarded to me a few worms collected in Macquarie Island, which lies to the south of New Zealand, about half-way between it and the land of the southern continent. These belong partly to the almost worldwide *Pachydrilus*, and one species—a new one—is referable to the earthworm genus *Acanthodrilus*. The importance of this latter species is that it is firstly an *Acanthodrilus*, and secondly that it is closely allied to a group of Patagonian and South Georgian species of the same genus, and is less like any New Zealand form. It is to me a matter of surprise that Dr. H. O. Forbes, in his recent and important essays upon this question, has ignored the distribution of earthworms, which are so thoroughly wedded to the soil, and (except in a few cases) so impatient of sea-water. I have attempted to rectify this state of affairs in a text-book of zoogeography, lately issued by the Cambridge University Press. In Patagonia and some of the islands immediately to the southward, only two genera of indigenous earthworms, so far as is known at present, exist. These are *Acanthodrilus* and *Microscolex*. Of the former there are nine species, and of the latter five; but five species of *Microscolex* and two species of *Acanthodrilus*, in addition to those referred to, range northwards into Chili, which zoologically is indistinguishable from Patagonia. Let me emphasise the point that these are the only two genera which occur in these latitudes, save for a species or two of the European *Allolobophoba*, which is universal in range—thanks probably to direct exportation by man. In Kerguelen and Marion Islands but one species of earthworms has been found, which is an *Acanthodrilus*. In New Zealand there are nine species of *Acanthodrilus*, also six species belonging to genera that are very nearly akin to *Acanthodrilus*, and three species of *Microscolex*. The remaining six species of *Microscolex* are South and Central American to the extent of four, while the two remaining are from Tenerife and Algeria. Of *Acanthodrilus*, the only species left, after deducting those already enumerated, are one from the Cape of Good Hope, one from New Caledonia, and three from Western and North Australia. Besides these forms New Zealand possesses a single Perichætid worm and Schmarda's species, *Hypogæon orthostichon*, which I have recently (a "Monograph of the Order Oligochæta," Oxford, at the Clarendon Press) referred to the characteristically Australian genus *Megascolides*. It is clear that, if the former northward extension of the Antarctic continent is not believed, some explanation of these remarkable facts is much wanted; on that hypothesis they are perfectly explicable.

Zoological Society's Gardens.

The Feeding Ground of the Herring.

I HAVE no desire to set aside lightly the observations of Profs. Herdman, Brady, Scott, or any other scientific gentleman, as suggested by Mr. Calderwood in your issue of November 21. There is no evidence that these gentlemen have made any systematic examination of the deep waters of Loch Fyne, whereas I have carried out investigations of this kind during many years at all seasons under the direction of Dr. Murray and Dr. Mill, and I think Prof. Herdman set these observations very lightly aside in his Ipswich address.

If various kinds of tow-nets be dragged through the surface waters of Loch Fyne, down to a depth of 20 fathoms, at the present time of the year, probably not a single specimen of red-coloured *Calanus*, *Euchæta*, *Nyctiphanes*, or *Boreophausia*, will be captured, and these animals I hold make up nine-tenths of the bulk of the food of the herring in Loch Fyne. If the same nets be dragged near to the mud at the bottom in depths between 70 and 100 fathoms, immense numbers of these Crustaceans will be taken; and this state of matters practically holds good throughout the whole year, these Crustaceans being always found at the bottom and rarely at the surface. It occasionally happens, however, that at quite local spots some of these deep-sea Crustaceans rise or are drawn up to the surface, and being carried out of their natural habitat are killed there, and are blown upon the shore, where they form a red line along the beach. It must be remembered, however, that this is quite an exceptional occurrence. On several occasions we wished to send to Inveraray living specimens of *Nyctiphanes*, in order that their brilliant phosphorescence might be exhibited. These were captured in large numbers in the trawl sent down to 70 fathoms, but we found that they were all killed as soon as they were put into the jars, which we afterwards found had been filled with the somewhat fresh water floating on the surface of the loch; it was only by collecting water from the deeper layers that a few specimens could be preserved alive. On other occasions, after a long spell of dry weather, there was no difficulty in keeping large numbers of *Nyctiphanes* alive for a long time, and on one occasion I conveyed many bottles filled with these Crustaceans to Edinburgh, and exhibited them at an evening meeting of the Royal Society.

The very fact that Mr. Calderwood was able to scoop up red-

[1] *Vide* NATURE, 1887, vol. xxxvi. p. 612. T. G. Bonney.

[2] "Variations Périodiques des Glaciers des Alpes." S. A. C. 1890, p. 358.

coloured *Calanus* on the beach with his hand, shows that these creatures had passed through some unfavourable conditions. Dr. Murray has endeavoured to show that these deep-sea animals are brought to the surface through the movements of large bodies of water during gales or during calms following gales. However this may be, their proper habitat is certainly at the bottom. When they do come to the surface they form oily-like streaks or small spots, where herrings and other fish and birds may be seen feeding upon them. The *Nyctiphanes* at any rate remain but a very short time at the surface. On one occasion in Kilbrennan Sound we were attracted to a spot where guillemots, gulls, and other birds were feeding, and we found that their stomachs were filled with perfectly fresh *Nyctiphanes*, and the *Nyctiphanes* themselves could be distinctly seen on the surface for a short time. The fishermen shot a circle trawl-net around this spot, and procured twelve boxes of herrings, the stomachs of which were distended with these Crustaceans in all stages of decomposition. I can show these stomachs to any one visiting this Station.

In my previous letter I mentioned that we had captured herrings in the deep water with their stomachs filled with these Crustaceans, and skate, which feed at the bottom, have been taken in depths over 50 fathoms with herrings in their stomachs. When the herrings' stomachs are filled with adult *Nyctiphanes*, as above stated, the herrings are not commonly called "gut-poke," or at least are not looked upon as diseased. The so-called disease is attributed to those herrings which have been feeding chiefly upon the young *Nyctiphanes*, or "black-eye."

I do not claim that there is anything new on this subject in my letters, nor do I see anything new in that of Mr. Calderwood, except the statement that Copepods alone are the cause of the the so-called "gut-poke" disease, which I do not believe. The whole of this information was published many years ago. In a lecture delivered in November 1887, as reported in the *Scotsman* of November 23, Dr. Murray said regarding the "poke-gut":—

"There was also a kind of herring called the 'poke-gut' herring, which was supposed to be suffering from some disease or complaint. This was a herring whose stomach was distended with food, which consisted of one or other of the minute animals to which he had referred. One of the commonest things to be told on the west coast was that the 'poke-gut' herrings were not fit for food, and would not cure. The fishermen told them that they had eaten some 'black stuff,' the effect of which was to make them sick, that it burned a hole in their bodies, and acts as if they had eaten quicklime. For a long time he was very doubtful as to what the explanation of this belief could be, but he ultimately found that the cause of it was this—that the poke-gut herrings had been feeding on the young *Nyctiphanes*. The eyes of these creatures are very black indeed (as Dr. Murray showed by exhibiting a bottleful of the creatures in a preparation of glycerine), and an accumulation of these in the stomach of the herring gave the whole contents a very black aspect. On being taken into the boat, decomposition set in very rapidly, the lining of the stomach was speedily eaten away, and before long an actual hole, as the fishermen said, was made in the body, out of which this black mass exuded. In this 'poke-gut' state the herring, however, was simply engaged in laying up a store of fat, the nutritive processes of the animal being then exceedingly active. When it had laid in this store of fat, the herring then sought the shallow waters of the shore for the purpose of depositing its spawn. Mr. Hoyle spent several months at Peterhead examining the stomachs of the herring to ascertain what they fed upon during the fishing season, but the result of his investigations was that he did not find in any one of them a full meal. Similar results were obtained by Mr. Beddard at Eyemouth, and by Prof. Herdman on the coast of Arran."

Our observations on board the *Medusa* went to show that the "poke-gut" condition of the herring was chiefly due to the large number of young *Nyctiphanes* contained in the herrings' stomachs, but Mr. Calderwood makes no mention of any Crustacea beyond Copepods. ALEXANDER TURBYNE.

Scottish Marine Station, Millport, Cumbrae, November 29.

The Theory of Magnetic Action upon Light.

I HAVE already pointed out that the various questions relating to the theory of the action of magnetism upon light cannot be disposed of by arguments based upon vague and obscure general reasoning, but require a careful mathematical investigation for their elucidation. I therefore propose in the present letter to state, as briefly as possible, the results to which an examination of Mr. Larmor's theory leads, and to show how my own theory may be amended so as to remove the objection concerning the discontinuity of the E.M.F at an interface.

I find that Mr. Larmor's theory requires that all the equations of Maxwell's general theory of the electro-magnetic field should remain unaltered, except the equation

$$P = -\dot{F} - d\psi/dx,$$

which must be modified by the insertion of the additional terms

$$-p_3\dot{g} + p_2\dot{h} + z\,d\phi/dy - y\,d\phi dz \;.\;.\;.\;.\;.\; (1)$$

where p_1, p_2, p_3 are constants depending on the magnetic field, and ϕ is a potential function.

The first two terms are equivalent to introducing Hall's effect; but for the last two there is no justification whatever. They are not required in optics nor in electro-magnetism. These results, combined with Larmor's boundary conditions, prove my statement that his theory makes the tangential component of the E.M.F. *discontinuous* at an interface.

In the next place, a satisfactory theory may be constructed by modifying Maxwell's relation between E.M.F. and electric displacement, keeping all the other equations unaltered. The proposed modification is

$$P = 4\pi f/\kappa + p_3\dot{g} - p_2\dot{h} \;.\;.\;.\;.\;.\;.\;.\; (2)$$

It will be found that this hypothesis leads to exactly the same equations of motion and boundary conditions as those given in my paper in the *Phil. Trans.*, 1891; but that, in consequence of the relation (2), the tangential component of the E.M.F. is *continuous* at an interface. The other boundary condition is, continuity of the tangential component of the magnetic force.

According to Maxwell's theory, the electrostatic energy is given by the expression

$$\tfrac{1}{2}(Pf + Qg + Rh);$$

and if we assume that this result holds good when P is given by the modified form (2), it will be found that all the results can be deduced by means of the principle of least action.

Under these circumstances, I think I may justly claim to have placed the theory of Kerr's experiments on as perfect a basis as is possible in the existing state of electrical science.

A. B. BASSET.

Fledborough Hall, Holyport, Berks, November 29.

The Barisál Gun.

I HAVE read with interest Dr. Darwin's communication, in NATURE for October 31, on "The Barisál Guns and Mist Pouffers," and his request that the readers of your journal should give accounts of their own experiences in this matter. I refer him to the *Theosophist* magazine, vol. ix. p. 705, and vol. xi. p. 409, for two articles upon my personal observations at Barisál village itself, in the Gangetic delta. All the various theories until then propounded by men of science to account for the phenomenon in question were severally reviewed and pronounced inadequate. I had intended writing a third and final article, but found it impracticable to throw any further light upon this most interesting problem, and so abstained. Dr. Darwin is quite wrong in supposing that the sound of the "Barisál Gun" is "dull and distant," and that "it does not resemble artillery." However the like sounds may seem to the Ostend lighthouse-keeper, they were so sharp and loud that I thought the "evening gun" was being fired at a cantonment in the village, and asked a friend standing by if that were so. I shall not encroach on your space to go into details, since the back volumes of the *Theosophist* may be consulted at the British Museum, and Dr. Darwin will make such use of them as he sees fit. H. S. OLCOTT.

Adyar, Madras, November 20.

Remarkable Sounds.

IN connection with Profs. McKenny Hughes and J. P. O'Reilly's letters on the above subject, suggesting the collection of data as to the distance the sound of blasting, &c., has been heard, it may be interesting to state that the blasting operations in the Charnwood Forest quarries (probably Bardon Hill) can be distinctly heard on the higher ground to the south-west of Atherstone, a distance of about eighteen miles. From the intensity of the sound, I have little doubt that under favourable conditions it may be heard very much further.

Geological Survey, Leicester. C. FOX-STRANGWAYS.

Flight of Birds Across the Moon's Disc.

ON the evening of October 7, 1895, while observing the passage of the moon through the Pleiades for occultations, my attention was attracted by a flight of birds across the moon's disc. This continued with more or less regularity the whole time I was at work, from 7.30 to 9.30, the birds usually crossing singly, but sometimes in groups of two, three, or even four. In all, I saw perhaps 50 or 60; assuming a like frequency during the intervals when I was not at the telescope, from 200 to 250 must have crossed the disc during the two hours. All were flying south with a single exception. Their outlines and the flapping motions of their wings were very distinct; none were soaring. The telescope is a 12-inch refractor: eyepiece of power 90. The moon was low, its altitude ranging from 5° to 15°.

The time occupied in transit varied from four to eight seconds, the difference in apparent size being very marked, and the larger always taking the less time. Assuming a rate of twenty miles an hour for their flight, the distance would be about 5 miles for a bird making a transit in eight seconds, or 2½ miles for four seconds. Taking into consideration the altitudes of the moon when the above transits were timed, the corresponding altitudes of the birds above sea-level ranged from 2700 to 5000 feet. Considerations as to its size make it probable that these figures are none too small. It may be of interest to note that the Observatory stands on a promontory jutting out about 5 miles from the general trend of the Syrian coast, and that according to these calculations the birds were flying either just along the coast-line or over the sea.

I may add that, in addition to Mr. Bray's experience, given in NATURE, No 1348, several accounts of similar observations are given in Newton's "Dictionary of Birds," with estimates of altitudes, ranging, for the most part, much higher than those given above.

ROBERT H. WEST.

Syrian Protestant College, Beirut, November 25.

A Luminous Centipede.

RETURNING home on a very dark evening a few days ago, I saw on the ground a greenish phosphorescent light which, in the distance, I took to be a glowworm (*Lampyris noctiluca*), but a nearer approach showed a luminous thread-like worm of 1¼ inches in length, moving in curves along the gravel drive. I stooped and placed a finger and thumb on either side of the glowing thread without actually touching it, and in a few seconds observed that, aware of danger either from scent or vibration, the insect showed a remarkable power of control over its luminosity, invaluable for protection. It began to extinguish its light, and in a most peculiar fashion, not dying slowly out all over, but with a rapid wave of darkness sweeping from the tail to the head, then in a second or so glowing brightly all over again, repeating the manœuvre several times so long as my finger and thumb remained in its vicinity. A glass was brought, into which I transferred the insect, where it glowed with a lessened light for three or four hours. The next night the phosphorescence was very feeble, and on the morning following the insect was dead.

Seen in the daylight my capture appeared to be a thin thread-like centipede, orange-coloured, furnished with a fringe of fine hairs on either side of its many-segmented body.

ROSE HAIG THOMAS.

The White House, Basildon, November 27.

THE above communication certainly refers to one of the luminous centipedes of the family *Geophilidæ*; and since the species that most commonly draws attention to itself in England by the exhibition of phosphorescence is of a reddish-orange colour and is known as *Linotænia crassipes*, there is no reason to doubt that the specimen under discussion was an example of this species. The property of luminosity lies in an adhesive fluid secreted by glands which open upon the lower surface of the body, and the power of discharging or retaining the fluid appears to be entirely under the centipede's control.

The phenomenon is observable during the autumn months, from about the middle of September to the end of November, and although its significance is not clearly understood, it is generally believed to be connected with the pairing of the sexes.

R. I. POCOCK.

The Critical Temperature of Hydrogen.

IN the October number of the *Proc. Phys. Soc.*, Mr. "G. H. B.," after quoting Wroblewski's paper "Die Zusammendrückbarkeit des Wasserstoffes" (*Wiener Sitzb.*, 1889), says (referring to my paper "On the Critical Temperature of Hydrogen," *Bull. Acad. Cracovie*, March 1895): "Natanson does not appear to have made any fresh experiments on the subject, and the conclusions arrived at in his paper are therefore not results of independent original investigation." It is difficult to understand the right Mr. "G. H. B." has to ignore the professedly *theoretical* character of my paper. To blame a writer offering theoretical deductions on the account of his not having made "fresh experiments," is surely a criticism of extraordinary character. Wroblewski's critical data are not in the least the outcome of direct experiment, but have been calculated from an empirical equation, constructed to represent Wroblewski's compressibility curves. My reasoning and calculation are *utterly different*, being founded upon Van der Waals' law of thermodynamic correspondence. Besides, there are other points in my paper, and they have no relation with whatever Wroblewski has written. All this will be seen at once on comparing my paper with that of Wroblewski's. But from Mr. G. H. B.'s own words, it must be inferred that, before publishing what implies a serious accusation, he did not take the trouble of looking with his own eyes at Wroblewski's paper.

LADISLAS NATANSON.

Cracow University, November 28.

A METEOR PHOTOGRAPH.

THE accompanying photograph (p. 132) was obtained on Saturday night, November 23, about 12h. 15m., by Mr. C. P. Butler, at Knightsbridge. With the intention of focussing and testing the field of a new lens, he had placed a quarter-plate camera on the window-sill, pointed it roughly at the region near the boundaries of Perseus, Andromeda, and Aries. He was necessarily in darkness during the exposure, but uncovered the plate about 12h. 10m., and terminated the exposure at 12h. 20m., so that the limits are close enough for recognising the meteor if it chances to have been recorded elsewhere, On developing the plate on the following Monday, the track of the meteor was the first impression to be perceived, and, not knowing of its occurrence during the taking of the photograph, it was thought that the plate had by some mishap been spoiled. Having finished developing, however, and after fixing, it was seen that this was not the case, the strange appearance being evidently an image of some meteor flashing past during the exposure. The star trails (the camera was fixed, so the stars are represented by short lines about an eighth of an inch long) are all distinct, but owing to the region included in the field being almost barren of bright stars, with the exception of α, β, and γ Arietis, which come in at the edge of the plate, they are too minute to bear reproduction.

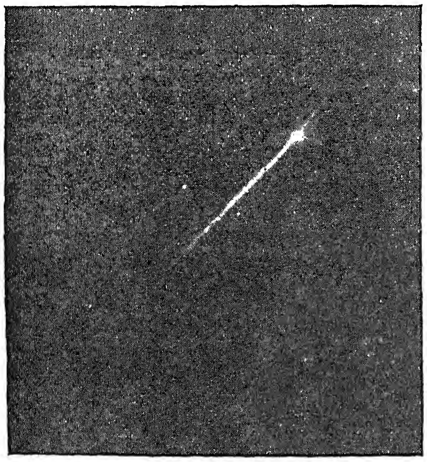
Confirmation of the occurrence of the meteor is given by its having been observed from the South Kensington Observatory, both the time of fall, 12h. 15m., and the estimated region of its path being identical with the above observations.

As near as can be estimated, on consulting the region on the star map, the meteor appeared some distance south of the interval between Perseus and Aries, in the area enclosed by α, γ, ξ^2 Ceti, and fell downwards. It would probably be one of the Andromedes, which were due to occur on the 23rd ult.

It was described as being as bright as Jupiter, and leaving a long trail. This is fully borne out on carefully examining the negative, or the accompanying enlargement, which is about six times the size of the original. Much additional light is thrown on the phenomena attending the passage of a meteorite through our atmosphere, as at present all that is known rests on the results of visual observations, which may be greatly deceptive in the case of such rapidly-moving objects.

The image, in comparison with those of stars of known

magnitude, proves the body to have been at least of magnitude -1, and at the time of greatest brilliancy this s probably an under-estimate.



PHOTOGRAPH OF A METEOR.

It begins very faintly, showing the initial contact with the atmosphere, and, gradually increasing in brilliancy until it has travelled about $1\frac{1}{2}°$; it is evident that about this time an explosion occurred, the details of which are well recorded on the photograph. The products of the detonation are seen spread out in all directions round the central mass, but the main portion again takes a definite path; not, however, in the original direction of the meteor's flight, as can be readily seen on reference to the photograph.

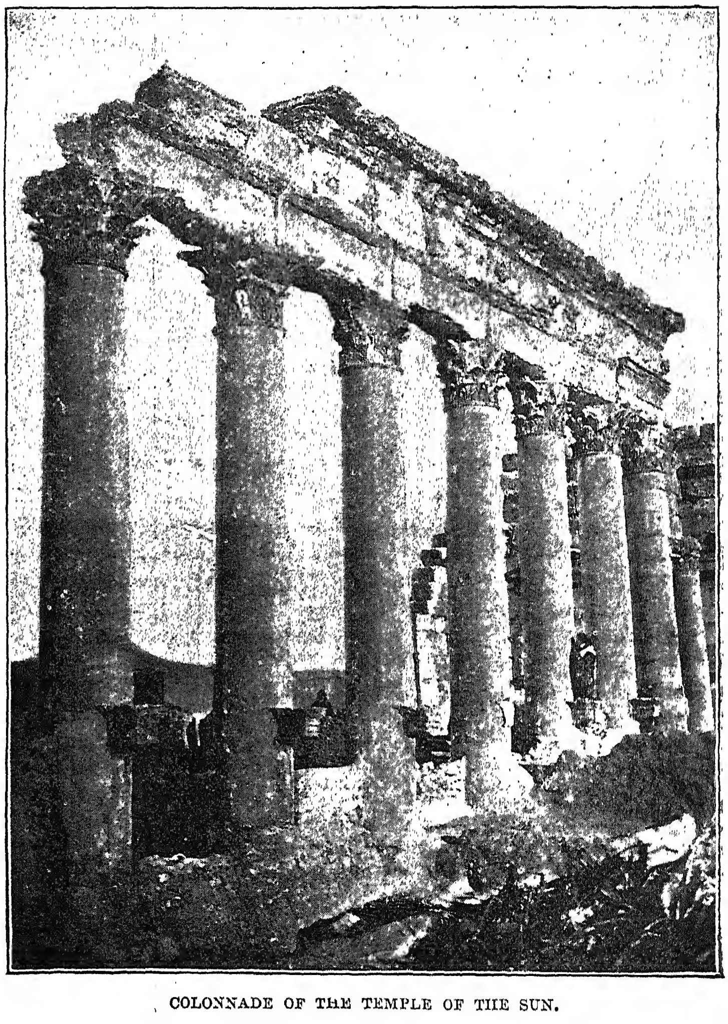
This is probably due to the body being of such a nature as to resist disruption in some directions more than others, and so the resultant of the initial velocity and the new velocity, due to the recoil of the main mass, might lie in some other direction than that of the original path. This has been the case here. If, as an approximation, we take its first appearance to have been at a height of sixty miles, the extreme diameter of the area occupied by the matter expelled during the explosion would be a little more than a mile. The brightest portion of the streak is about $3\frac{1}{2}°$ long, but the fainter trail may be traced for a considerable distance beyond, becoming at last too faint to affect the sensitive plate.

THE ROYAL CITY OF ZENOBIA.[1]

LIKE all ancient cities of the East that have once been centres of trade and culture, but are now only marked by piles of ruins and a few squalid huts, Palmyra has a strange fascination. Though on the edge of the Syrian desert, the site of this ancient city is but five days' journey from Damascus, so that her ruins have been thoroughly explored, her inscriptions copied, and all facts that might be of interest to the man of science, the archæologist, or the historian, have been obtained from her. On opening Dr. William Wright's "Palmyra and Zenobia," therefore, we did not look to find anything very startling or original.

From internal evidence of his work, we gather that Dr. William Wright, who must not be confused with the late Prof. William Wright of Cambridge, is connected with a Protestant missionary society, and from his preface we learn that he was resident in Syria for nine years. It was, perhaps, in consequence of his duties at Damascus that he was unable during this period to break fresh ground in his excursions from that city, and had to be content to follow the more beaten tourist track. His book, in fact, contains an account of two visits to Palmyra, one in 1872, the other in 1874; and as neither of these was of very long duration, we must congratulate him on the production of the present work. The latter part of the book records a trip to the south of Damascus as far as Bosra.

His account of his experiences on the road is amusingly told, and to many will be novel, for Syria is not yet so well known as Switzerland; but what Dr. Wright regards as "adventures," would perhaps appear to the veteran explorer as somewhat ordinary incidents of travel. His description of the ruins, however, and his sketch of the history of Palmyra, though a little superficial and wanting in arrangement, is in the main trustworthy and will, no doubt, prove attractive to many readers. On one occasion the author drops his *rôle* of gossipy narrator, and inserts on p. 124*f.* two Palmyrene inscriptions, to

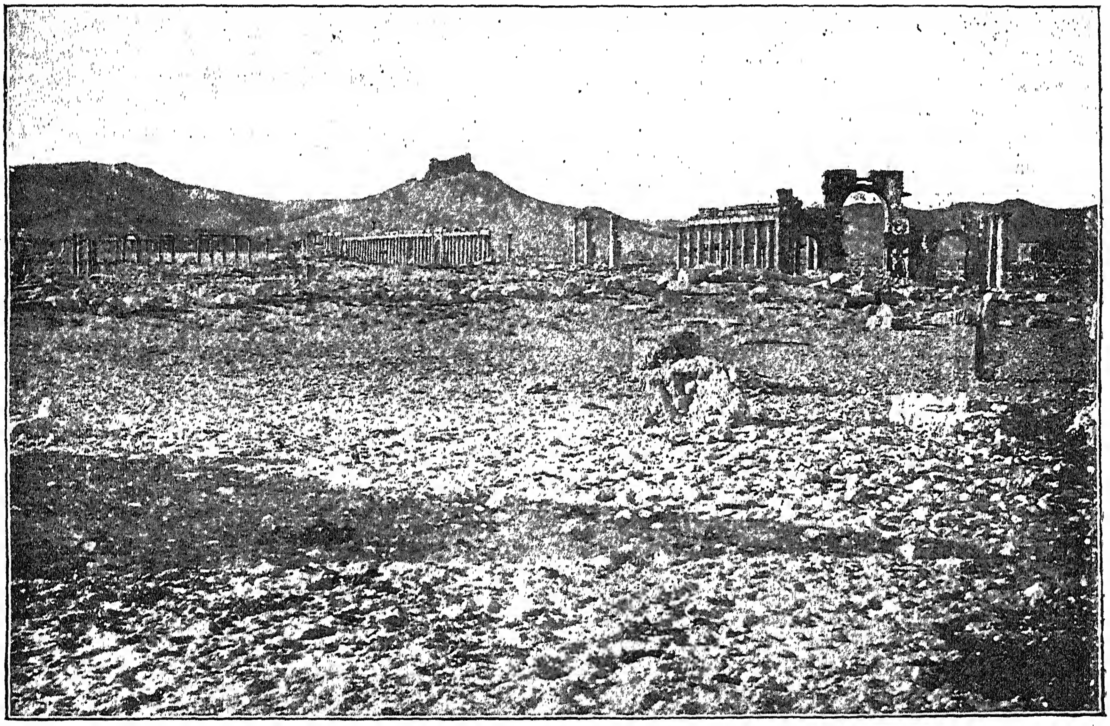


COLONNADE OF THE TEMPLE OF THE SUN.

[1] "An Account of Palmyra and Zenobia, with Travels and Adventures in Bashan and the Desert." By Dr. William Wright. (London: Thomas Nelson and Sons, 1895.)

which he appends translations. The inscriptions appear to have been reproduced from De Vogüé's "Syrie Centrale," pl. 4, Nos. 28 and 29, and the translations are versions of the French rendering to be found on p. 28 *f.* of the same work. We do not blame Dr. Wright for this apparently learned insertion, as no doubt many of his readers would be interested in seeing what a Palmyrene inscription looks like; but we do think he should have given some reference or indication of the source from which he took his information. It is the more to be regretted that he omitted to do this, as in his translation Dr. Wright has written "the daughter of *Zabbai*" for *Bath-Zebhīnah* of the original, not recognising the proper name, Ζηνοβία, in its semitic dress—an odd mistake to come across in a book which claims to give an account of that great queen.

In a book of travel one does not expect any remarkable purity of style, but Dr. Wright has perhaps too great a liking for fine language; as, for instance, when he describes a lady out riding as "bounding over the desert on a splendid charger, whose neck of thunder swayed hither and thither to her silken touch." But this is a minor detail, and, although we cannot honestly say that the man of science or antiquary will gather any particularly new or useful information from his pages, it would be ungenerous to discourage any one from describing, for the benefit of other people, the places and incidents from which he himself has derived pleasure. The book, in fact, would form a chatty and by no means uninteresting companion to any more solid work on the same subject, such as Socin's "Palestine and Syria," published by Baedeker, in which all historical and topographical facts concerning Palmyra and Syria in general are carefully arranged. We may add that the volume before us is prettily bound, well printed, and has plenty of illustrations, two of which are here reproduced. The one gives a view of a colonnade from the Temple of the Sun at Palmyra, while from the other some idea can be obtained of the forest of columns which are still standing on the site of that once famous city.



TRIUMPHAL ARCH, WITH CASTLE IN THE DISTANCE.

NOTES.

THE Council of the Pasteur Institute are about to organise a committee to make an international appeal for funds to erect a statue of Pasteur in Paris.

AN expedition to observe the solar eclipse next August will be sent out to Yezo from Amherst College, U.S.A., under the direction of Prof. David P. Todd. The expedition is expected to leave San Francisco next spring.

IT is reported by Reuter that steps are being taken to invite the Prince of Wales and the Secretary of State for the Colonies to visit Toronto in August 1897, when the British Association meets there, to open the new municipal buildings, which by that time will have been completed at a cost of £500,000.

AN Electrical Lighting and Power Act has recently been passed at the Cape of Good Hope, authorising regulations for the safety of the public. Mr. A. P. Trotter has been appointed Government Electrician and Inspector under this Act.

THE deaths are announced of Dr. A. J. Woïtow, Professor of Bacteriology at Moscow; Dr. Ludwig Rütimeyer, Professor of Zoology at Basel; Dr. F. P. Porcher, of Charleston, South Carolina, author of numerous works on pharmaceutical botany.

THE Executive Committee of the City and Guilds of London Institute are inviting applications for the appointment to the Salters' Company's Research Fellowship for the ensuing year. The Fellowship was founded by the Salters' Company for the encouragement of higher research in chemistry in its relation to

manufactures, and particulars of the scheme under which the award is made may be had on application to the Honorary Secretary, at the head office of the Institute, Gresham College, Basinghall Street, E.C. The results of the researches by Dr. Martin O. Forster, the Salters' Research Fellow for the current year, at the Institute's Central Technical College, were communicated to the Chemical Society at its last meeting.

A NUMBER of the former students of Prof. Bonney's Geological Classes at the University of Cambridge, and at University College, London, have united to present him with his portrait as a memento of their personal esteem, and in recognition of his labours among them, and of his services to geological science. The portrait will be presented to Prof. Bonney on Monday, December 16, at 3.30 p.m., at University College, Gower Street. The work has been executed by Mr. Trevor Haddon, of the Abbey Studio, 18 Great George Street, Westminster, where it will be on view on Friday and Saturday, December 13 and 14, from 10 to 4. A platinotype reproduction of the picture has been prepared under the supervision of the artist, who will be glad to afford further information.

THE following are among the lecture arrangements at the Royal Institution before Easter:—Prof. J. G. McKendrick, six lectures (adapted to a juvenile auditory), on sound, hearing and speech; Prof. Charles Stewart, eleven lectures on the external covering of plants and animals: its structure and functions; Prof. H. Marshall Ward, three lectures on some aspects of modern botany; Lord Rayleigh, six lectures on light. The Friday evening meetings will begin on January 17, when a discourse will be given by Lord Rayleigh, on more about argon; succeeding discourses will probably be given by Prof. Burdon Sanderson, Mr. W. S. Lilly, Dr. John Murray, Mr. J. J. Armistead, Dr. Edward Frankland, Mr. A. R. Binnie, Mr. Sidney Lee, Prof. T. R. Fraser, Prof. Dewar, and others.

THE Government of India has resolved to establish an imperial bacteriological laboratory at Agra, under the directorship of Prof. Hankin, and an imperial chemical laboratory in Calcutta. According to the *British Medical Journal*, health officers are to have a six months' training in bacteriology; special diplomas, after careful training in hygiene, are to be granted by the colleges, and 1900 municipalities will be expected to appoint trained men for sanitary work. To make the scheme complete, further laboratories will probably be organised on a smaller scale in each of the great Indian presidencies, and arrangements will be made for giving six months' training of medical officers in the service. The scheme, when completed in details and in course of time, will give to India a perfect sanitary organisation and service.

THE fireball of November 22, which formed the subject of letters in NATURE of November 28 and December 5, attracted the attention of a large number of observers. Mr. W. B. Tripp, writing from Isleworth, says the meteor was observed there at about 6.50 p.m. Mr. J. H. A. Jenner noted the spectacle at Lewes at the same time, and remarked that the trail was visible for two or three minutes, and remained quite straight until it disappeared. He adds; "The path of the meteor was along the eastern sky from south to north, following a line from about the centre of the constellation Perseus towards α Ursa Major. The colour of the ball itself was reddish, and the motion seems to have been comparatively slow." This meteor was seen also at Chichester and Dover. At the latter place, the time noted by Mr. W. H. Pendlebury was 6.53 p.m., and the light emitted was said to have been "sufficiently brilliant to throw the electric light into shadow, while the glow remained visible for between one to two seconds."

FROM a letter addressed to Mr. R. H. Scott, by Dr. J. Hann, we are glad to learn that the Austrian expedition for the Society's exploration of the Red Sea has succeeded in establishing meteorological stations at Jedda, Kosseir, and Brothers Islands, about forty miles off the coast of Upper Egypt, and has provided them with self-recording barometers. At the latter station the observer is a Norwegian, in charge of the lighthouse. It is hoped that the observations will be continued for at least two years, and will furnish an important contribution to the meteorology of the district. Observations have been made at the Dutch Consulate at Jedda for some years, and by the Italians at Massowa, but, generally speaking, observations at land stations in those parts are scarce. The expedition will investigate the southern parts of the Red Sea, between Jedda and Massowa, during the winter months, and we learn that the zoological collections have up to the present time been very satisfactory.

ZOOLOGISTS will be glad to note that the editor and publisher of the *Zoologischer Anzeiger* have recently announced the steps which they are prepared to take in conjunction with Dr. Haviland Field towards a reform of existing bibliographical methods. With the new year the *Zoologischer Anzeiger* will be to some extent remodelled. It will retain its present mode of publication in approximately fortnightly numbers, as well as its division into two sections, independently paged, one dealing with scientific communications, and the other with current literature. But complete volumes of the *Anzeiger* will no longer take the form of annuals. They will be determined simply by bulk: forty sheets of "Wissenschaftliche Mittheilungen" and forty sheets of "Litteratur" will together compose a volume. The "Litteratur" section, moreover, will be obtainable in three different forms: (1) the ordinary edition, (2) an edition printed on one side of the paper only, and (3) a ticket-edition, suitable for the formation of card-catalogues. The two first editions of this "Bibliographia Zoologica" will be issued from the office of the *Zoologischer Anzeiger* in Leipzig, but the ticket-edition will be exclusively issued from the office of Dr. Field's International Bibliographical Bureau in Zürich. This combination of Dr. Field's and Prof. Carus's forces should prove of great service to students of every branch of zoological literature, which in these latter days has attained such enormous dimensions.

IT is now nearly twenty years since the brilliant, if brief, career of *Bathybius* was extinguished by the discovery that this primordial organism was in fact no organism, but a colloid precipitate of calcium sulphate produced by the action of alcohol on sea-water. Ten years later, however, *Bathybius*, or its next of kin, seemed to come to life again in the form of a remarkable protozoon parasite discovered by M. Moniez in the body cavity of certain small fresh-water Crustaceans (Ostracoda and Cladocera), and named by its discoverer *Schizogenes parasiticus*. This creature was described as an irregularly shaped disc of homogeneous, slightly refractile protoplasm, which showed no differentiation into zones and contained no nucleus, no contractile vacuole, and no granule of any kind. It was stated to exhibit a certain power of movement, and to reproduce itself by fission or constriction. It would appear, however, that *Schizogenes* is not to escape the fate of its more illustrious predecessor. Dr. G. W. Müller, well known by his monograph on Ostracoda in the Naples series, has found that the *Schizogenes* of the Ostracoda is no organism, but the viscid chitinous secretion of the so-called shell-gland. (*Zool. Anz.*, No. 486.) The secretion shows the different shapes and movements characteristic of *Schizogenes* owing to the absorption of water. *Schizogenes* can, in fact, be created at will by compressing the fresh shell-gland of an Ostracode in water beneath a cover-slip.

IT has been shown by several investigators that luminous vibrations of short wave-length are capable of producing an inflammation of the skin. It is, therefore, easy to understand

that such actinic rays increase an inflammation already existing, as is the case in small-pox. The latest contribution to the knowledge of this action appears in the *British Medical Journal*, in which Dr. N. R. Finsen, of Copenhagen, gives the results obtained by keeping small-pox patients in non-actinic light. The following are the main points concerning the treatment:—(1) The exclusion of the chemical rays must be absolute; even a brief exposure to daylight may produce suppuration and its sequelæ. In other words, the skin during small-pox is as susceptible to daylight as a photographic plate, and must be kept from the chemical rays in the same way and almost as carefully. If, therefore, red window glass is employed, it is necessary for it to be of a deep red colour, and if curtains are used, they must be very thick or in several layers. When the patient takes his meals, or during the physician's rounds, artificial light—for instance, faint candle-light—may be used without any danger. (2) This method does not prevent but allows the employment of any other treatment which may be considered necessary. (3) The treatment should be commenced as early as possible; the nearer the commencement of the suppuration the smaller the chance of success. (4) The patient must remain in the red light until the vesicles have dried up.

ONE of the difficulties which attends the production of the new serum remedy for diphtheria is the uncertainty which accompanies the elaboration of toxic products by the diphtheria bacilli in culture media. This diphtheria-toxine, as it is called, has to be produced on a large scale, and it must be of a requisite degree of virulence, or it will not, when subsequently inoculated into horses, endow the blood-serum of the latter with the necessary degree of diphtheria-immunising properties. Even the bacilli taken direct from the throat of a diphtheria patient are not capable of elaborating, in culture media, toxines of a sufficient strength for the purposes of anti-diphtheritic serum production, and recourse has to be had to increasing their virulence by first inoculating them into guinea-pigs, and then transferring them to the culture media. The reason of this most inconvenient idiosyncrasy, so characteristic of diphtheria bacilli, has until recently not been surmised, but Prof. Spronck of Utrecht has unravelled the mystery in a most interesting manner.

THE last number of the *Archives des Sciences Biologiques*, published by the Imperial Institute of Preventive Medicine in St. Petersburg, gives the annual report on the anti-rabic inoculations carried out during the past year in St. Petersburg and Odessa respectively. In St. Petersburg, 224 persons were treated by Pasteur's method, and only three succumbed to hydrophobia. In two of these cases death ensued during the treatment and before, therefore, the inoculations had produced their full effect; in the other case, the patient was not treated until thirteen days after he had been bitten, and he died just three weeks after the inoculations had been completed. Amongst the rabid animals, 193 were dogs, 18 wolves, 7 cats, 5 horses, and 1 pig. At Odessa, no less than 984 persons were inoculated anti-rabically, the larger number of persons so treated being between twenty-one and forty years of age. The death-rate from hydrophobia, including those persons who died before the treatment was completed, was equal to 0·32 per cent. An instance is recorded of a death from hydrophobia having taken place one year after the anti-rabic inoculations were completed. The patient was severely bitten on his hands by a mad dog, and presented himself a week later at the Institute, although the wounds had been cauterised three hours after their infliction; the inoculations were completed on July 14, 1893, and on July 15, 1894, he died of hydrophobia. At Odessa the largest number of cases were admitted in the months of May, June, and July; but at St. Petersburg, contrary to the usual experience, the maximum number of patients were received in the spring and autumn respectively.

A NUMBER of interesting observations of the habits of the common bat and the long-eared bats in captivity are recorded by Mr. John D. Batten in *Nature Notes* for December. Common bats appear to be practically blind, yet Mr. Batten mentions that he never knew a bat fly against a window or against any obstacle: light or darkness apparently making no differences in its flight. Long-eared bats appear to see better than common bats, and their hearing is much more acute. There is seldom any difficulty in inducing bats to feed. Mr. Batten fed his bats at first on flies, moths and grasshoppers, but when these became scarce, he fed them almost entirely upon meal-worms. It is remarkable that bats, on being captured, readily adopt an entirely new method of life, and the new habits thus acquired quickly become natural. When bats are asleep in October and November, they take sometimes as long as a quarter of an hour to awaken. Mr. Batten has observed the process carefully, and finds it to be always the same. He thus describes it: "The bat when thoroughly asleep is cold, dead cold to the touch. If I then took it in my hand it would not attempt to move about or seek for food, but lie quite still. On putting it to my ear I could hear a throbbing begin, at first very slowly and not very regularly, more than a second between the beats. Gradually the throbbing became quicker and quicker until it was impossible to count the beats, at the same time the warmth of the body was increasing very rapidly, and the bat quivering visibly. At last the throbbing becomes a continuous whirr, not unlike the purring of a cat, and the body feels quite hot to the hand. Then, rather suddenly, the throbbing quiets down like water coming to the boil, it slows somewhat, and becomes almost inaudible. The bat coughs or sneezes, chatters a little with its teeth, and begins to move about expecting to be fed." Of three bats set to hibernate at the end of November in 1890, two were found dead at the end of the following January, and one was alive and perfectly strong; its fur was in good condition, and it fed well, and the hibernation had not affected its power of flight.

THE occurrence of perlitic cracks in a rock of stony texture has always been held as evidence of its alteration from an originally glassy state; but within the last two years doubt has been cast on this conclusion through Mr. W. W. Watts's observations on the pitchstone of Sandy Braes, in which perlitic cracks were claimed as traversing the quartz and other crystals as well as the matrix. In a paper read before the Royal Society of New South Wales, Mr. W. F. Smeeth has, in connection with a description of a local pitchstone resembling that of Sandy Braes, discussed fully the exact mode of origin of perlitic cracks and the features which distinguished them from other curved cracks. He points out that the artificial perlitic structure that can be made in a Canada balsam film is a "two-dimensional phase of the natural structure," and from its characters he tries to deduce those of the tri-dimensional phase. His conclusion is that natural perlites are "cracks of more or less irregularly spiralloid character, occurring in the interspaces between sets of polygonal cracks." Allowing for irregularities due to want of homogeneity in the lava, and for the fact that, whereas in the artificial structure the axes of the spirals are all normal to the surface of the film, the axes of the natural spiralloids are variable in direction, he deduces a series of possible figures for sections of true (tri-dimensional) perlitic structure. The most obvious of the characteristics shown by these theoretical sections is that the curves never meet otherwise than tangentially. That these theoretical figures are actually those seen in sections of typical perlitic rocks, affords strong evidence of the correctness of the views suggested as to their mode of formation. Passing on to consider the curved cracks in the quartz-crystals (shown by the New South Wales specimen as well as by that described by Mr. Watts), he points out that the cracks, instead of meeting one

another tangentially, do so at marked angles, and are therefore not truly perlitic; while he shows how these also can be imitated artificially. Reasons are given for doubting the perlitic character of cracks in lithoidal rocks claimed as such, and finally the author considers it "extremely improbable that a crystalline aggregate, consisting of individuals with various cleavages and different coefficients of contraction, would be able to develop so delicate a structure" as the true perlitic.

THE *Naturwissenschaftliche Wochenschrift* of November 17 contains a summary of some of the most important preliminary results of forty-seven balloon ascents made in Germany between June 1888 and February 1895, compiled from communications by Dr. R. Assmann in various scientific journals. In four of the ascents the balloons contained self-recording apparatus only, and of the other forty-three cases, M. Berson, an assistant in the Meteorological Office at Berlin, made thirty-six ascents (in four of which he was quite alone), and Lieut. Gross made twenty-eight ascents. The heights attained in some of the voyages were the greatest yet recorded. It was found: (1) That the air-temperature above 4000 metres was considerably lower than had been theoretically assumed, or deduced from earlier ascents. This apparently points to the fact that in the earlier ascents the thermometers were affected by solar radiation, while in the recent ascents this defect was obviated by the use of the aspirator invented by Dr. Assmann. (2) That the assumption that the decrease of temperature with height was most rapid in the lower strata of air, is untenable; the decrease was found to be fairly uniform with increasing altitude, and the isotherm of 32° F. was found to lie between 3600 and 3800 metres. (3) That the stratum between 2000 and 4000 metres was relatively too warm, owing to the greater condensation of clouds in those regions. (4) That the seasonal variation of temperature was very small above the height of 6000 metres. (5) That the inversion of temperature during winter, and at night time, up to the height of 1000 metres, appeared to be a regular phenomenon. (6) That cumulus clouds were at times found at unexpected altitudes. (7) That the surface of a massive layer of cloud affected higher strata of air thermically and electrically, like the surface of the earth. (8) That the electrical potential decreased with height, pointing to the earth as the sole source of atmospheric electricity. (9) That the aqueous vapour was unexpectedly small in even moderately high regions of the air, the variation in amount between two layers of cloud being often very great. The balloon ascents have been temporarily discontinued, with a view to discussing the existing materials.

THE Cryptogamic journal *Grevillea*, which has been published at irregular intervals since Dr. M. C. Cooke resigned the editorship, will not appear again. The papers which were intended for it have been transferred to the *Journal of Botany*, still under the editorship of Mr. James Britten. This journal will be published monthly as heretofore, but will be increased in size from thirty-two to forty-eight pages.

THE Report of the Department of Botany at the British Museum for 1894, by Mr. W. Carruthers, shows that many interesting additions were made to the Herbarium during the year, one of the most important being the collection of freshwater Algæ made by the late Dr. A. H. Hassall, which includes a number of type specimens. Collections of flowering and flowerless plants have also been obtained, by donation, exchange, or purchase, from all parts of the world, especially from British India and from our other colonies.

MR. F. N. WILLIAMS has issued a provisional and tentative list of the orders and families of British flowering plants, founded on the system of classification of certain continental botanists. He proposes to divide Phanerogamia into three "phyla," Angiospermæ, Anthospermæ, and Gymnospermæ, the second of these consisting of one family only, the Loranthaceæ. The Angiospermæ are again divided into two classes, the Dicotyledones and Monocotyledones; the Dicotyledones consist of two subclasses, the Sympetalæ (Tetracyclicæ and Isocyclicæ) and the Choripetalæ (Eucyclicæ, Phalangiata, Aphanocyclicæ, Calyciflora, Centrospermæ, and Archichlamydeæ). The whole range of flowering plants is further grouped under 42 orders and 110 families.

APPENDIX II. of the *Bulletin of Miscellaneous Information* of the Royal Gardens, Kew, is devoted to a list of the New Garden Plants of the year 1894. It includes not only plants brought into cultivation for the first time during the year, but also the most noteworthy of those which have been reintroduced after having been lost from cultivation, and some which had not previously been properly described. In addition to species and botanical varieties, all hybrids, whether introduced or of garden origin, but described for the first time in 1894, are included. The number of hybrids is especially noteworthy in *Cypripedium* and other genera of *Orchideæ*. The total number of names in the list is about 500.

AN absolutely black body is one which both radiates and completely absorbs radiations of any wave-length. It is practically impossible to prepare such a body by artificial blackening; but Messrs. W. Wien and O. Lummer have invented a body which answers all requirements in the way of perfect blackness. This quality is impaired by reflection of any kind from the surface, and hence the inventors take care that the body in question shall be supplied with exactly those kinds of radiation which it reflects, and which its radiation lacks in consequence. The interior of a hollow sphere at any uniform temperature is in a perfect condition in this respect, since there is perfect equilibrium between the heat received and given out. By making an opening at one point, this state is only slightly disturbed, and the inside of the hollow sphere will act as a perfectly black body. From a disquisition which appears in *Wiedemann's Annalen*, it appears that the authors propose to use this body and a bolometer to test Boltzmann's law, which makes the radiation proportional to the fourth power of the absolute temperature.

Industries and Iron has commenced the issue of a series of portraits of eminent workers in the field of engineering science. Two portraits have already appeared as supplements to our contemporary—one of Lord Armstrong, in the issue of November 29, and the second, of Sir Douglas Fox, in the issue of December 6.

THE December number of *Science Progress* contains an account, by Dr. D. H. Scott, F.R.S., of the late Prof. Williamson's researches on the carboniferous flora. Other papers included in the number are on mineral transformations, by Mr. H. A. Miers; some applications of the theory of osmotic pressures to physiological problems, by Dr. E. Starling; theories of electrolysis, by Mr. C. Dampier Whetham; recent papers treating of the Upper Palæozoic beds, by Mr. Marr; and a notice of the discoveries and researches of the great physiologist, Carl Ludwig, by Dr. Leon Asher.

SOME of our readers may be interested in an ingenious puzzle which has been devised by Mr. W. Radcliffe. It consists of three sets of discs of equal sizes, each set containing the seven principal colours of the spectrum; and the problem is to arrange nineteen of these so that there will be seven groups of the same size and shape, each group containing the seven different colours. Notwithstanding that there are 5040 possible solutions to this "seven-colour puzzle," the result is by no means easily attained. It should furnish a useful exercise for young children in distinguishing colours.

THE American Ornithologists' Union held its thirteenth annual congress in Washington at the middle of last month. We understand from the New York *Nation*, that a new feature was a special memorial session, at which the late Mr. G. N. Lawrence was eulogised by Mr. D. G. Elliot, and the late Prof. Huxley by Dr. Elliott Coues. The regular scientific sessions were opened by an exhibition of unpublished water-colour paintings by Mr. Louis Agassiz Fuertes, a student of Cornell University, on whom some of the members seemed to think that the mantle of Audubon himself had fallen. Mr. W. T. Blanford was promoted from corresponding to honorary membership, and Mr. W. H. Hudson was admitted to the former. Mr. William Brewster, of Cambridge, succeeded Dr. Coues in the presidency, and the Union meets at Cambridge, Mass., next year.

THE recently-published number of the *Proceedings* of the Liverpool Geological Society (vol. vii. part 3) contains the address on "Chemistry as an Aid to Geology," by Mr. Dickson, the retiring President. He points out, among other things, the value of chemical analyses in tracing the source of drift-deposits, and particularly insists on the importance of discriminating between true *clay* and the *rock-flour* which commonly passes by the same name. Other papers in the same number deal with matters of local geology, including descriptions of new railway cuttings near Seacombe, and a moraine in the Brecknock Beacons. An important discovery of abundant *Lepidostrobi*, exhibiting various stages of development, and in actual connection with the branches of *Lepidodendron*, is recorded from St. Helens by Mr. Lomas, who also contributes an account of the Faroë Islands.

MESSRS. C. W. FAULKNER AND CO. have sent us a number of specimens of their Christmas publications, including Christmas cards, photogravure pictures, calendars, and games. What connection there is between these things and science may not be very clear at first sight. We are so used to calendars that we forget that time was when men had to look to the skies "for signs, and for seasons, and for days and years." This duty is now relegated to astronomical observers and computors, while the average man concerns himself with more mundane affairs. The pictures upon the Christmas cards are not gaudy abominations, but attractive reproductions from photographs of bits of scenery; they should remind people of the gifts of science to art, and, with the photogravure pictures, they show what excellent illustrations can now be obtained by photographic processes. As to the new games received in Messrs. Faulkner's packet, they are ingenious and offer means of pleasant relaxation from mental work.

THE first number of the *Scientific African*, which has come to hand, gives promise of a useful existence, as an exponent of South African science, arts, and crafts. The journal has a large region, full of objects and wonders of transcendent interest, as its sphere of influence. It can do much to stimulate scientific observation, and in its pages one may hope to find valuable information on the animals, minerals, and industries of South Africa. We notice in the number before us an article in support of the geological survey of Cape Colony, showing that the immediate undertaking of the survey is necessary: (*a*) in the interests of pure science, (*b*) in treating the land, (*c*) for the sake of the water supply, (*d*) for the development of the mineral resources. There is also an article on the white-tailed wildebeest or gnu, accompanied by a photograph of a male and female contained in the Selous collection in the South African Museum. Among other contributions are articles on natural gas and petroleum, a biographical notice (with portrait) of Dr. P. D. Hahn, an account of the Brandolei hot spring near the city of Worcester, South Africa; several letters, science notes, a notice of Pasteur, and a brief report of the British Association meeting at Ipswich. We wish the new journal a long and successful life.

THE forty-fifth volume of the *Jahrbuch der k.k. Geologischen Reichsanstalt* opens with a valuable series of analyses made in the laboratory of that institution by C. von John and C. F. Eichleiter. The first group of analyses are of coals of various ages and from various localities in Austria. The rest comprise ores, sedimentary rocks, water, metals, &c. This is followed by a paper on the distribution of the minerals in the lodes of Strebsko near Pribram. Kerner contributes a description of some Cretaceous plants from Lesina, which are of interest owing to the abundance of Cycadeæ. Felix Karrer issues two further instalments of his studies on the Cainozoic deposits of the Vienna basin. Dr. F. E. Suess gives the results of his investigations as to the earthquake which occurred around Neulengbach, near Krems on the Danube, on January 28, 1895. He discusses previous shocks in the same district, and concludes that the transverse axis of this earthquake area follows the strike of the mountains. C. Zahalka discusses the stratigraphical position of the "Bischitzer Uebergangsschichten," which Anton Fric regarded as the lowest member of his Iserschichten group. Zahalka divides the Bohemian chalk into ten zones, and on Fric's view the Bischitzer passage beds would belong to zone No. 8 of this series. The author, however, maintains that it belongs to his zone No. 4, or the Upper Drinowèr Knollen of Fric; that is to say, in English terminology it is transferred from the Senonian to the Lower Turonian. A second important paper on the Bohemian Chalk is contributed by J. J. Jahn, who advances the important conclusion that the Iser Schichten of Eastern Bohemia, are only a local representative of the Teplitzer Schichten, instead of being a distinct formation and of an earlier age.

Bulletin vol. ii., No. 4, of the College of Agriculture, Imperial University, Tokio, Japan, contains much gratifying evidence of scientific activity in the Far East. Dr. Oscar Loew, the professor of agricultural chemistry, continues his paper on "The Energy of the Living Protoplasm," and Mr. G. Daikubara has a second paper on "The Reserve Protein in Plants." Then follow four papers by Mr. Y. Kinoshita, dealing severally with the consumption of asparagine in the nutrition of plants, the assimilation of nitrogen from nitrates and ammonium salts by phænogams, the presence of asparagine in the root of *Nelumbo nucifera*, and the occurrence of two kinds of mannan in the root of *Conophallus konyaku*. Mr. K. Yoshimura has a note on the chemical composition of some mucilages, and makes incidental reference to the facts, of industrial importance, that the mucilage of *Sterculia platanifolia* and of *Kadzura japonica* is used in Japan for sizing paper, and that the tuberous rootstock of *Colocasia antiquorum* serves as a valuable food in Japan, where it is largely cultivated. Mr. M. Inouye deals with the preparation and chemical composition of *tofu*, which consists principally of the protein-matter of the soya bean, is said to be as easily digestible as beef, and can therefore be used to make up the deficiency of proteids in rice, the staple food of man in Japan and China. The same author has a note on *nukamiso*, which is rice-bran in a state of lactic fermentation, and is used to soften certain vegetable foods, such as the radish and the fruit of the egg-plant, which are rendered palatable and easily digestible when left in a large quantity of *nukamiso* for about twenty-four hours. Mr. J. Cho answers in the negative the question, Does hydrogen peroxide occur in plants? Mr. Yoshimura, previously mentioned, has a note on the behaviour of hippuric acid; he concludes that decomposition of hippurates proceeds more quickly in the surface soil than in the subsoil, that it is attended with liberation of ammonia, and that it is chiefly dependent upon the action of micrococci.

THE additions to the Zoological Society's Gardens during the past week include an Arabian Baboon (*Cynocephalus hamadryas*) from Egypt, presented by Mrs. Locke King; two Tufted Umbres (*Scopus umbretta*) from Bechuanaland, South Africa, presented by Mr. F. J. Newton, C.M.G.; four Cockateels (*Calopsitta novæ-hollandiæ*), a Many-coloured Parrakeet (*Psephotus multicolor*), a Rose-Hill Parrakeet (*Platycercus eximius*) from Australia, presented by Mr. Thomas J. Manns; two Red and Blue Macaws (*Ara macao*), five Saffron Finches (*Sycalis flaveola*), two Pileated Song Sparrows (*Zonotrichia pileata*), a Guttural Finch (*Spermophila gutturalis*), a Plumbeous Finch (*Spermophila plumbea*), a White-throated Finch (*Spermophila albogularis*), a —— Finch (*Spermophila torqueola*), a Black-throated Siskin (*Chrysomitris magellanica*) from South America, a Brambling (*Fringilla montifringilla*), a Greenfinch (*Ligurinus chloris*), European, presented by Mr. A. J. Chalmers; a Red-vented Bulbul (*Pycnonotus hæmorrhous*) from India, presented by the Hon. Miss E. Dillon; a Chestnut-breasted Finch (*Donacola castanothorax*) from Queensland, presented by Mr. A. Rowney; a Hardwick's Mastigure (*Uromastix hardwicki*) rom India, presented by Mr. W. Allen; a Black Swan (*Cygnus atratus*) from Australia, deposited; two Black-necked Stilt Plovers (*Himantopus nigricollis*) from South America, a Green-headed Tanager (*Calliste tricolor*) from South-east Brazil, purchased.

OUR ASTRONOMICAL COLUMN.

THE NEW COMETS.—Numerous observations of Perrine's Comet and a few of Comet Brooks are reported in *Ast. Nach.*, No. 3320. The former is generally described as bright, the nucleus being about 7th magnitude, while the tail is pretty broad, and variously estimated at from 10′ to 20′ in length. From observations up to November 25, Dr. E. Lamp finds the date of perihelion passage to be 1895, Dec. 18·3509 Berlin mean time, and the following ephemeris is given:—

	R.A. h. m. s.	Decl. ° ′	Brightness.
Dec. 11	15 59 40	−24 7·6	28·30
12	16 16 14	26 2·1	
13	34 33	27 50·5	
14	16 54 40	29 25·0	
15	17 16 5	−30 37·4	60·0

The unit of brightness is that on November 18. The comet is brightening with great rapidity, but it is so near the sun that observations can only be made in daylight.

Comet Brooks apparently presents only the appearance of a feeble, diffused nebulosity without condensation. The following ephemeris for Berlin midnight is due to Dr. H. Kreutz:—

	R.A. h. m. s.	Decl. ° ′	Brightness.
Dec. 12	7 16 42	+57 23·5	0·8
13	7 0 37	59 45·8	
14	6 43 39	61 48·0	0·6
15	26 4	63 31·2	
16	6 8 2	64 56·7	0·5
17	5 49 52	66 6·2	
18	31 47	67 1·4	0·4
19	5 14 6	67 43·7	
20	4 57 4	+68 15·0	0·3

The brightness on November 24 is taken as unity. According to the elements adopted, perihelion was passed on October 20·887.

It will be seen that the comet is now circumpolar.

THE GREAT COMET OF 1843.—In the *Astronomische Nachrichten*, No. 3320, Dr. Kreutz gives another chapter in the history of the three interesting comets of 1843 I., 1880 I., and 1882 II., all belonging to one cometary system, distinguished by great brilliancy and small perihelion distance. In 1889, Dr. Kreutz published an exhaustive monograph on the motion of the 1882 comet, that one of the system which, it will be remembered, was first seen in this country by Dr. Common, in bright daylight, and which at the Cape was followed till it seemed to touch the sun's limb. The present inquiry has reference to the 1843 comet, also seen and observed in full daylight, and the motion of which had been made the subject of a classical discussion by Dr. Hubbard (*Astronomical Journal*, vols. i. and ii.). The improved normal places which Dr. Kreutz has formed are not, however, very well represented by Hubbard's orbit, and new elements have been derived, which, of course, do not differ materially from the earlier results. The period, deduced as the most probable, is 512 years, or twenty years less than Hubbard's period; but the interesting point in the present discussion is the determination of several orbits with various values for the semi-axis major, assigned on the hypothesis that this comet of 1843 is identical with some other the appearance of which has been recorded. The periods assigned are thirty-six years, suggested by a possible identity between the 1843 and 1880 comets; 175 years, which would make the 1843 comet a reappearance of that in 1668; 800 years, a period approximately equal to that found for 1882 II., and finally a parabolic orbit. The result is to settle very decisively that there is no identity between the 1843 and 1880 comets, and almost as certainly that the comet is not a return of that of 1668. On the other hand, it is by no means certain that equal periods would not satisfy the observations in both 1843 and 1882, but true parabolic motion cannot be accepted. From the position of the line of intersection of the orbital planes of the two comets 1843 and 1882, Dr. Kreutz infers that they originally formed one comet, and that the separation into two distinct bodies was effected near the time of perihelion passage. Seeing that the 1843 comet would approach within 100,000 miles of the sun's surface, it is easy to suggest a cause for the subdivision.

NEBULOSITIES AROUND THE PLEIADES.—The nebulous relationships of the Pleiades, brought so forcibly into view by the beautiful photographs of Dr. Isaac Roberts, are carried a stage further by a photograph which we owe to Prof. Barnard. This was taken with the 6-inch portrait lens with a total exposure of 10h. 15m. on December 6 and 8, 1893, and an enlargement and description of the plate are given in the current number of *Knowledge*. In this photograph the nebulæ photographed by Dr. Roberts are submerged in the "burnt out" images of the brighter stars; outside the group various nebulous masses and streams are seen extending in all directions, but apparently connected with the nebulosities of the cluster itself. The most prominent of the new nebulosities are two irregular streams flowing from the north and south sides of the cluster, and running three or four degrees easterly; the northern stream is double for a part of its length, but the upper part is very feeble. The nebulosities have also been photographed by Dr. Wilson, of the Goodsell Observatory, with an exposure of 11 hours; they are best seen by increasing the contrast in a positive copy of the plate.

THE FIRST STEPS IN SERUM-THERAPY.

IN scientific discovery, as in many other walks of life, it frequently happens that the magnitude of the result achieved casts into obscurity the labours which led up to that discovery, just as the parent is often forgotten in the fame which may subsequently surround the work of his offspring. It is rarely, however, that so young an infant as we must perforce recognise antitoxic serum to be, succeeds in baffling the pedigree-hunter; barely recognised three or fours years back, its parentage has, however, already become the subject of much discussion.

Dr. Welch, of Baltimore, in an exhaustive paper[1] on the treatment of diphtheria by anti-toxin, commences with an historical survey of the subject, and states that Babès and Lepp in 1889 were the first to publish results of experiments to solve the question whether the fluids and cells of animals which have been rendered immune by vaccination, have not become vaccines and capable of protecting also other organisms. On turning, however, to the volume of the *Annales de l'Institut Pasteur*, in which the memoir by Babès and Lepp[2] on this subject is published, we find that they do not claim to have originated these investigations, for they expressly state: "We have seen, in the course of our investigations, that this problem has been studied experimentally in various diseases, and this fact encouraged us to pursue this idea."

[1] "The Treatment of Diphtheria by Antitoxin," *Trans.* Association of American Physicians, vol. x., 1895.

[2] "Recherches sur la vaccination antirabique," *Annales de l'Institut Pasteur*, vol. iii., 1889.

In the address on Pasteur, delivered before the British Association at Ipswich, Prof. Percy Frankland distinctly attributes this discovery to Héricourt and Richet. He said: "This astounding antitoxic property of the blood-serum of an artificially immunised animal was first discovered by Héricourt and Richet in respect of animals immunised against one of the common abscess-producing organisms."[1]

Now Dr. Welch goes out of his way in a foot-note reference to Babès and Lepp to mention that "Richet and Héricourt are sometimes quoted as the first experimenters to show that the blood of animals is capable of conferring protection upon susceptible animals, but their work *has no reference to modern serum-therapy, as their experiments were made with the blood of dogs which had not previously been vaccinated or treated in any way.*"

If we refer to the *Comptes rendus* for 1888, we shall find a paper by Héricourt and Richet entitled "Sur un microbe pyogène et septique (*Staphylococcus pyosepticus*) et sur la vaccination contre ses effets." In this memoir the authors describe their experiments on procuring immunity in rabbits towards this organism by inoculating them with weakened cultures of it. They conclude by saying: "The methods which we have used to procure these vaccinations are those in general use by Pasteur and his pupils. But we have conceived of a new method (the peritoneal transfusion of a dog's blood into rabbits), a process which also produces vaccination; in a subsequent communication we shall describe in detail the results obtained by this method."

It is this subsequent paper which has been entirely overlooked by Welch and other investigators. Strange to say, also, there is absolutely no reference to it in the *Centralblatt für Bakteriologie*, although a very incomplete abstract of the earlier paper did appear in this journal. This second communication, to which, in the light of recent scientific investigations on the use of antitoxic serum, much interest and importance attaches, is entitled "De la transfusion péritonéale, et de l'immunité qu'elle confère" (*Comptes rendus*, 1888, p. 748).

The following passage, taken from this memoir, will perhaps most clearly convey some idea of what results were obtained by Héricourt and Richet in these first investigations in serum-therapy:—"On October 4, seven rabbits were inoculated with four drops of a culture of the *Staphylococcus pyosepticus*, six having received 48 hours previously some dog's blood in the peritoneum. The control animal[2] died in less than 20 hours after the inoculation. Of the six others, three died, one 50 hours, the other 70 hours, and the third 90 hours after the inoculation. The three others survived; they are still alive at the present time. To explain the apparent inconsistency of these results, it must be noted that the transfused blood was obtained from two different sources: first, from a dog which had never been experimented upon—the rabbits which received this blood did not survive the inoculation; secondly, from a dog which had survived inoculation made some months previously with the *Staphylococcus pyosepticus:* the three rabbits which received this blood survived the subsequent inoculation with the *Staphylococcus pyosepticus.*" These results were confirmed by further investigations, proving, as the authors say, that it was not "un fait exceptionnel." In the course of their experiments Héricourt and Richet found that the blood of untreated dogs did endow rabbits with a certain degree of protection from subsequent inoculation with this micro-organism, inasmuch as the course pursued by the disease in the case of these rabbits was distinctly modified, being less virulent and less rapid, but they expressly state that they consider the assumption justified that the blood of dogs inoculated with this *Staphylococcus*, is capable of conferring immunity of a more complete nature than that obtained by using the blood from untreated dogs.

It is sufficiently apparent, therefore, that these experiments of Héricourt and Richet, far from having "no reference to modern serum-therapy," are the original investigations from which the antitoxic treatment of disease by means of blood-serum has directly followed.

The authors conclude this most interesting memoir by expressing the hope that the injection of the blood of an animal endowed with a natural power of resisting a particular disease may possibly be able to protect other animals, not so fortunately endowed, from attacks of this disease. So far, however, this hope has not been realised. In an article entitled "Recent Studies on Diphtheria" (NATURE, August 22, 1895, p. 393), it was pointed out how the natural or race immunity of one animal to a particular disease was not capable of being transferred, by means of its blood-serum, to another animal susceptible to this disease. We read: "This remarkable circumstance has been once more very clearly demonstrated by Wassermann in the case of diphtheria, to which disease white rats are absolutely immune. In order to test the character of white-rat-serum as regards diphtheria infection, fatal doses of diphtheria toxin were administered to guinea-pigs along with such serum, but in no case did the latter survive, showing that this serum possessed no anti-diphtheritic properties whatever, and was incapable of protecting animals from diphtheria infection."

In connection with the wider application of anti-toxic serum in the treatment of disease, it is interesting to note that already in 1889 Messrs. Babès and Lepp experimented with it successfully in the treatment of rabies, obtaining the anti-toxic serum from a dog rendered artificially immune to hydrophobia. So far, but little advance has been made with it in this direction; since, however, scientific attention has been so attracted to this subject by the success which has attended the use of anti-toxic serum in diphtheria, we may certainly anticipate many fresh developments in its beneficent application.

[1] *Times* Report, September 17, 1895.
[2] Not previously inoculated with dog's blood.

THE MAJOR PREMISS IN PHYSICAL CHEMISTRY.[1]

CHEMISTRY is essentially an inductive science, mathematics is essentially deductive, while physics holds an intermediate position. Yet in our own science, generalisations are reached from time to time, which serve as major premises for syllogistic reasoning. For example, the proposition that each portion of matter has constant weight is at the basis of our knowledge of chemical equivalents as determined by the balance; the isolation of the metals of the alkalis and alkaline earths led to an insight into the nature of salts in general as metallic compounds; and the "periodic law," though not expressed in precise mathematical language, is a most fruitful generalisation of generalisations.

Physical chemistry, following the logical methods already so largely adopted in physics, is characterised by a readiness to use the major premiss. Instead of making a separate experiment to answer each question of fact, the conclusion may often be reached on theoretical grounds, in the same sense as an engineer may demonstrate the stability of the structure he has designed, or the movements of a newly invented machine. What, then, is the leading major premiss in modern chemistry? and what shall be the conditions of fruitfulness?

The doctrine of energy, as based upon thermo-dynamics, embraces the two laws of conservation and correlation; first, energy (while convertible from one form to another) is constant in amount; second, while work may be wholly converted into heat, only a definite fraction of heat can be converted into work. To specify more clearly, if a quantity of heat, H, is received at temperature T (from absolute zero), and if this is converted into work as far as possible by any ideal process until there remains the quantity H′ at temperature T′, then the simple theorem holds that the two quantities of heat are proportional to the two temperatures; and of course the difference between heat received and heat remaining (that is, the work) is proportional to the difference in temperature. Or in algebraic language,

$$H : H' :: T : T'$$
$$H : H-H' :: T : T-T'$$
$$\text{Work}, = H-H' = \frac{T-T'}{T}.H$$

This equation shows what *fraction* of the heat may be converted into work, under the most favourable conditions; namely, the fall in temperature divided by the absolute temperature at which the heat is supplied.

My present purpose is to present this topic in its bare outlines, and with the greatest simplicity possible. Those who wish to follow the deductive reasoning in detail must use the notation of the calculus, in accordance with the following steps. Combining the formula for the total work (as implied in the first law) with that for work derived from change of temperature (the second

[1] Abstract of a paper prepared by request, to introduce the topic of Physical Chemistry, for the American Association for the Advancement of Science. Read September 2, 1895. (Reprinted from *Science*.)

law), we deduce a differential equation for the work obtained or required in isothermal changes. The change under consideration may involve external work, as when a vapour or gas is generated against atmospheric pressure; or it may be internal work of different kinds, as when the molecules are endowed with increased kinetic energy in volatilising, or when a compound is decomposed into its constituents, with increased potential energy.

A somewhat difficult but important paper by J. Willard Gibbs[1] treats of the equilibrium of heterogeneous substances, giving deductions from the two laws of thermo-dynamics, which in turn become major premises for a host of further deductions; so broad, indeed, are the propositions of Gibbs, that the distinctions between chemistry and physics do not appear; there may be two "heterogeneous substances" of like chemical nature, as water and its vapour; there may be three chemical bodies, as limestone with the lime and the carbon dioxide obtained by ignition; or there may be several physical mixtures, as solution of water in ether, solution of ether in water, and the mixed vapour resting upon both liquids. Now, a little consideration will show the importance of knowing when equilibrium is established, for this is equivalent to saying that no further action can take place; the solution is saturated, no longer acting upon the salt; or the gas which has been generated under pressure is no longer evolved. When a change takes place spontaneously, as when I drop a stone, or mix sulphuric acid with water, heat is developed from some other form of energy. To reverse the process, work must be done. The conversion of heat into work is limited by natural law; when a given change implies the doing of work, and that work is forbidden by the terms of our major premise, the change is impossible, equilibrium prevails.

"Osmotic pressure" in dilute solutions is analogous to the pressure of gases; the Gay-Lussac-Marriotte law, with slight modification of terms, applies to molecules in the liquid state. If work is required to diminish the volume of a gas by means of pressure, work is likewise required to diminish the volume of a body in dilute solution, whether the solvent be removed by evaporation or by freezing. Boiling point and freezing point of the solvent are changed by the presence of the dissolved body. The agreement of observed facts with theoretical deductions has led to important methods of determining molecular weights, while the apparent discrepancies in the case of electrolytes have proved an important argument for the doctrine that these compounds are dissociated into their ions.

The mutual indebtedness of technology and pure science has already been pointed out. Manufacturing processes afford many examples of change which are not carried to completion; it is important to know how far the operation can be improved to afford a larger yield, a purer product or less waste. Combustible gases issue from the blast furnaces. There is still a great reducing power in this mixture of carbon monoxide with carbon dioxide. Can it be utilised by enlarging the furnace? Immense furnaces were built in order to secure a larger yield of iron, but the results were disappointing. The law of mass action shows that the equation

$$Fe_2O_3 + 3CO = 2Fe + 3CO_2$$

is limited by certain conditions of equilibrium, and that the ratio of the two oxides of carbon could not be greatly improved over that already secured in practice. The expense of a technological experiment might have been saved, had the indications of mathematical chemistry been heeded.

What hopeless confusion seems to prevail in our present knowledge of solubilities; yet how important in the separations required for chemical analysis. Here, again, we deal with questions of equilibrium. Will work be done at the expense of heat or not?

There are two special difficulties in the general application of thermo-dynamical principles: first, the minor premise is often wanting; and, second, the mathematical form of reasoning is often difficult for the best laboratory workers. Among the published data of thermo-chemistry, some have been determined directly, some indirectly; it is often difficult to find the data desired, or to judge of their accuracy. A critical compilation of all available thermal data, conveniently arranged for reference, with at least some indication of the probable errors, would be very desirable. Many such data might be computed indirectly from experimental determinations of equilibrium. Many empirical equations have been computed, showing solubility as a function of temperature. Who will trace the correlation among such, and thus add a large chapter to thermo-chemistry? What genius shall discover that form of mathematical function that shall substitute rational for empirical equations with a clear interpretation for each constant required? "But this work is mathematical rather than chemical," you will say. Yes, it is applied mathematics; and mathematicians (not being chemists) are not likely to undertake such a task for us, unless we ask their counsel and aid. Specialisation is inevitable; yet by too arbitrary a specialisation, we may inadvertently lose the very help we need. Again would I emphasise the fruitfulness which follows a "cross-fertilisation of the sciences" (*Journ. Amer. Chem. Soc.*, 15, 601 (1893). Judging from the advances recorded in late years, especially in the *Zeitschrift für physikalische Chemie*, it is safe to predict great developments for the rising generation. I heartily echo the sentiment that we need more data; yet great stores of observations upon record have not yet been coordinated and put to use. Ostwald, desiring to know the influence of free iodine upon a reduction process, made three series of determinations (twenty-four in all) from which he concludes that the influence is *not* proportional to the mass. It was no part of his purpose to discover what the law of retardation is; but others might well follow out this clue, using also the data supplied by Meyerhoffer, and supplementing these with further experiments if needed. A glance at the literature of solubilities, and the lack of rational formulæ to express broad generalisations, may convince us that a great mine, with abundant ore "in sight," is awaiting development; or, rather, that ore has been run through a stamp-mill to extract half the gold, while fully half still remains in the tailings, awaiting more perfect methods of treatment.

Much may be learned from the systematic habits of the astronomer, dividing his work among the several observatories in a spirit of helpful co-operation, and assigning the labour of computation to those who are fitted thus to follow the lead of others. What better service can we do for the University student than to set before him some of the problems in mathematical or physical chemistry that require patient toil, and give him the pleasure of assisting in their solution by the use of logarithms and squares? What is more practical than to utilise any service he can render?

In conclusion, I beg leave to suggest the appointment of a joint Committee (representing Sections A, B and C of the American Association) to consider the feasibility of striving towards the following ends:

(1) The compilation of all reliable data of physical chemistry in convenient form for reference, distinguishing those determined directly from those calculated indirectly.

(2) The calculation of empirical formulæ, to combine any series of data, when some better form of generalisation is not already at hand.

(3) The preparation and use of rational formulæ, wherever possible, to deduce the natural constants from series of observations, and to express the conditions that may be expected to hold between observations of different kinds.

(4) The organisation of a band of volunteer compilers and computers from among advanced students, who (with the counsel and aid of their instructors) may assist in the work of compiling data and computing formulæ.

While the time did not seem ripe for the appointment of such Committee at the late meeting of the A. A. A. S., the writer would be pleased to receive any further suggestions from those interested, regarding the points noted above.

ROBT. B. WARDER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—At the 160th meeting of the Junior Scientific Club, held on Wednesday, November 17, the following officers for next Term were elected:—President, E. C. Atkinson; permanent treasurer, D. H. Nagel; treasurer, N. V. Sidgwick; biological secretary, R. Warren; chemical secretary, H. P. Stevens; editor, A. W. Brown; committee, R. A. Baddicom, M. Hesketh, T. J. Garstang. It was announced that Prof. W. Ramsay had consented to deliver the fifth Robert Boyle Lecture in the Summer Term, 1896.

CAMBRIDGE.—The late Mr. James Carter has bequeathed his collection of fossil Crustacea, on which he was a recognised authority, to the Woodwardian Museum. A portrait of the late

T. Sterry Hunt, Hon. LL.D. of the University, has been presented to the same Museum by Mr. Douglas, of New York.

The Walsingham Medal, given annually by the Lord High Steward for an essay on a biological subject, has been awarded to Mr. I. L. Tuckett, Fellow of Trinity College. Essays for the next award are to be sent in to Prof. Newton, by October 10, 1896.

Dr. Joseph Griffiths has been appointed an Examiner in Surgery.

The Special Board for Medicine propose a new scheme for the degree of Master in Surgery, whereby the degree will be open to M.A.s and B.C.s who have made contributions of sufficient merit to the advancement of the science or art of surgery.

Prof. J. G. McKendrick, F.R.S., has been appointed an Elector to the Chair of Physiology, in the place of the late Prof. Huxley.

A grant of £50 has been made by the State Medicine Syndicate to the Department of Pathology, in aid of the course of bacteriology there given.

The Agricultural Science Syndicate report an increase in the number of candidates for the University's diploma in agriculture. All of the candidates at the recent examination were trained in Cambridge, and one of them obtained the silver medal of the Royal Agricultural Society. Seventeen students, all of them members of the University, are now attending the courses provided in the sciences bearing on agriculture. The fees for the examination are not yet sufficient to meet the expenses.

THE Calendar (1894-95) of the Imperial University of Japan, which has come to hand from Tokyo, should be seen by all who desire to know something about the history of that University, and the work that is being done. The number of professorial chairs in the several Colleges appears surprisingly large to those who are not familiar with the character of the University. There are twenty-three chairs attached to the College of Medicine, twenty-one to the College of Engineering, seventeen to the College of Science, and twenty to the College of Agriculture, not to mention those in the Colleges of Law and Literature. From each of the Colleges valuable memoirs on special researches have been issued, and the University seems to be carrying out the objects of its founders, viz., "the teaching of such arts and sciences as are required for the purposes of the State, and the prosecution of original investigations in such arts and sciences."

MR. WILLIAM TATE, of the Royal College of Science, South Kensington, has been appointed Professor of Chemistry at the Civil Engineering College, Sibpur, Calcutta.

PROF. R. A. SAMPSON has been appointed to the chair of Mathematics in Durham University, vacated by the resignation of the Rev. R. J. Pearce.

THE parts of the University of Virginia destroyed by fire are being rebuilt. *Science* states that reconstruction of the Rotunda, the central building of the group recently destroyed, has already been begun. The necessary money to do this, about £16,000, has been practically subscribed. It is proposed to build a general academical building costing £18,000, a physical laboratory costing £6000, a building for mechanics and engineering costing £6000, and a building for the law school costing £4000. Governor O'Ferrall has promised to recommend in his message to the State Legislature a prompt and liberal appropriation to repair the losses of the school, and it is hoped that £40,000 will be received from this source. Appeals are being made to friends of the University and of education to contribute to the rebuilding and enlargement of the University.

The annual meeting of the National Association for the Promotion of Technical and Secondary Education was held on Tuesday, the Duke of Devonshire being in the chair. After the eighth annual report of the Association, presented by Sir Henry Roscoe, had been adopted, the Duke of Devonshire opened a conference of representatives of technical education committees of county and borough Councils. The subjects discussed were evening continuation schools, the award and tenure of scholarships, and trade and technical classes.

SOCIETIES AND ACADEMIES.

LONDON.

Institution of Civil Engineers, December 3.—Sir Benjamin Baker, K.C.M.G., President, in the chair.—The Influence of Carbon on Iron, by Mr. John Oliver Arnold. This paper embodied the results of researches undertaken by the author primarily to determine whether, at high temperatures, the carbon still remained in combination with the iron. A series of eight 3-inch square crucible-steel ingots, ranging in carbon between 0·08 per cent. and 1·47 per cent., the total impurities other than carbon averaging 0·2 per cent., were hammered and rolled to $1\frac{1}{16}$ inch diameter. They were then submitted to chemical, mechanical, microscopical, thermal, and magnetic tests, in three standard physical conditions, namely: normal, or cooled in air; annealed, or very slowly cooled; and hardened, or very rapidly cooled. The differential analyses for carbon confirmed the conclusion arrrived at by the author in a previous research, that the hard plates of Sorby's laminæ consisted of pure crystallised Fe_3C; and under certain conditions contained practically the whole of the carbon present in the steel. The mechanical tests showed that in normal steels the tenacity increased with carbon up to 1·2 per cent., a further addition of carbon causing a diminution in the stress. The ductility of normal steel diminished with the carbon; the elongation with 0·1 per cent. of carbon being 47 per cent., and at 1·5 per cent. 3 per cent. on 2 inches. Under compression the softness of normal steel decreased with the carbon until 0·9 per cent. of that element was present. Annealed steels under compression indicated a maximum hardness at 0·9 per cent., and were distinct softer than the normal metals. Steel with 1·5 per cent. of carbon was softer than iron containing 0·1 per cent. In hardened steels the rigidity of the metals increased enormously as the carbon rose. The microscopical investigation showed that pure iron consisted of cubic and octahedral crystals. The general results of the microscopical examination sustained the theory that the hardness of quenched steel was due not to a hard allotropic modification of iron, but to a definite sub-carbide corresponding to the formula $Fe_{24}C$. The magnetic observations on hardened steels had led the author to the conclusions that (1) the magnetic permeability varied inversely as the carbon present; (2) the permanent magnetism was directly proportional to the carbides of iron present; and (3) in iron containing between 0·1 per cent. and 0·9 per cent. of carbon the permanent magnetism was directly proportional to the sub-carbide of iron present. The author based the existence of a sub-carbide of iron, possessing the formula $Fe_{24}C$, to which the phenomena of hardening and tempering were due, on the following experimental facts: (1) the well-marked saturation points in the micro-structure of normal, annealed, and hardened steels; (2) a sharp maximum in a curve, the co-ordinates of which were heat evolved or absorbed at the carbon change point, Ar. 1, and the carbon percentage; (3) a point in the compression curve of hardened steels at which molecular flow ceased; and (4) a sharp maximum in a curve, the co-ordinates of which were the carbon percentage and permanent magnetism in hardened steels.—The Dilatation, Annealing, and Welding of Iron and Steel, by Mr. Thomas Wrightson. This paper dealt with investigations of some of the physical changes which occurred in iron during its passage from the homogeneous molten state to the solid and more permanent condition. With regard to the alleged floating of solid iron upon molten iron of the same kind, the author had found that if the piece of solid iron was lowered into the liquid metal by means of an iron fork, it always descended with the fork, but in a few seconds left the prongs and floated to the surface. For some time the sphere continued to rise above the surface until, at such a temperature that it melted, it quickly joined the molten metal. On first sinking the ball proved itself to be denser than the liquid iron. It then expanded and became considerably less dense than the liquid; and lastly, a reversal took place and the ball in melting became of the same density as the liquid. The assumption that dilatation was continuous and uniform during the passage from the liquid to the solid state was therefore erroneous. In order to eliminate the errors due to the emergence of the floating body above the surface of the molten metal, the author used for subsequent experiments an instrument by which the specific gravity of a 4-inch cast-iron ball, completely submerged in the metal, could be observed and continuously recorded. A specimen of the record obtained from the apparatus was given. Experiments upon grey Cleveland iron showed that the specific gravities of the cold solid iron, molten iron, and of plastic iron, were 6·95, 6·88, and 6·50 respectively; and that in passing from the solid to the plastic condition, the iron underwent an increase of volume of 6·92 per cent., followed by a quick contraction as it became liquid. The order of experiment was afterwards reversed, and the change of volume was measured as the molten iron solidified. Into two spherical moulds of dried

loam, 15 inches in diameter, was poured in one case Cleveland white-iron, and in the other Cleveland grey-iron. The fluid metal first entirely filled the mould. An expansion of the outer layers then took place as the metal became plastic, the diameter of the ball therefore increasing. The liquid interior, not having commenced to expand, sank in the hollow shell formed by the cooling and expanding layers of the outside, and thus formed a cavity at the top, which was shown in a photograph of the cross-section of the ball. The metal round the inner surface of the top cavity then hardened, and the interior liquid metal expanded gradually towards the centre; and, by its pressure on the soft outer envelope, also tended to increase the diameter of the ball. This action continued until the outer layers arrived at such a temperature that they should contract; when a contest arose between the contracting force of the fast-thickening outer layers and the expanding force of the interior as it in turn became plastic. When these forces balanced each other, further expansion was arrested. After this point in the cooling had been reached, the outer layers contracted as far as their condition wou' allow, but not to the full natural extent, as, while the outside was in a state of tension owing to the swelling of the interior, fresh layers of plastic and solidifying metal had been built up in the interior. By the time contraction had commenced, these had formed an arch of many courses under different degrees of tension; and such a structure tended to prevent the free contraction of the whole mass. The interior of this enlarged vessel then contracted and drew away principally from the upper part owing to the mass of plastic iron tending to gravitate to the bottom of the ball. The results of further experiments on the buoyancy of solid rolled low-carbon steel showed that it followed the same law as cast-iron. It appeared, therefore, that the physical changes from liquid to solid, as from solid to liquid, were similar in grey-iron, white-iron, and low-carbon steel. In view of the apparent analogy between the expansions of cast-iron in cooling from the liqu' d to the plastic condition and the expansion of water in cooling from 4° C. to 0° C., the author had undertaken experiments to ascertain whether the welding of iron could be attributed to similar action to that producing regelation in ice. To identify the two phenomena, it must be proved that the surface of the iron at the moment of welding contracted with increase and expanded with decrease of temperature. But as, according to the reasoning of the late Dr. James Thomson, matter possessing this property m ist also be cooled by impact or pressure, the identification would be complete, if this collateral property of the cooling of welding iron under pressure could be demonstrated. In the author's experiments, which were carried out at the Mint, with the aid of Prof. Roberts-Austen, the temperature at the welding surface of iron heated in an electric-welding machine was taken by a Roberts-Austen recording pyrometer. The results were given of a series of five experiments, in three of which a fall of temperature, ranging between 19° C. and 57° C., had resulted from the application of pressure, at temperatures of between 1300° C. and 1420° C. The thermal expansion of iron was therefore negative between 1300° C. and 1420° C. The theory of regelation in ice was founded on the fact that the melting-point was lowered by pressure. This held good also for iron, in which case, however, there were increasing degrees of mobility between the temperature of 1400° C. and that of melting wrought-iron, 1600° C. When pressure was applied to a bar, *e.g.* at 1400° C., not only was the melting-point lowered, but the mobility of all lower temperatures within the critical condition was increased.

Chemical Society, November 21.—Mr. A. G. Vernon Harcourt, President, in the chair. The following papers were read:—The influence of temperature on refractive power, and on the refraction equivalents of acetylacetone and of ortho- and para-toluidine, by W. H. Perkin, senr. The author ascribes the discrepancies between his own and Brühl's values for the refraction equivalents of acetylacetone, the toluidines, &c., at high temperatures, to experimental error in the use of Brühl's refractometer.—The evolution of carbon monoxide by alkaline pyrogallol solution during absorption of oxygen, by F. Clowes. The author has determined the experimental conditions regulating the evolution of carbon monoxide during the absorption of oxygen by pyrogallol solution, and details the precautions to be taken for the accurate estimation of oxygen by the absorption method.—The composition of the limiting explosive mixtures of various combustible gases with air, by F. Clowes. The compositions of the limiting explosive mixtures of air with methane, hydrogen, carbon monoxide, ethylene, water-gas, and coal-gas are very different; the narrowest limits are observed in the case of methane, the widest in that of hydrogen.—Note on the estimation of butyric acid, by W. H. Willcox.—Some derivatives of anthraquinone, by E. Schunck and L. Marchlewski. The three isomeric methylpurpuroxanthins and several of the ethers of anthraquinoneoxime have been prepared. — Efflorescence of double ferrous aluminium sulphate on bricks exposed to sulphur dioxide, by D. Paterson. The white asbestos-like efflorescence which appears on bricks exposed to sulphur dioxide, has the composition $Al_2(SO_4)_3$, $FeSO_4$, $24H_2O$, and is evidently identical with a salt found in volcanic regions.

Entomological Society, December 4.—Prof. Meldola, F.R.S., President, in the chair.—Mr. S. H. Scudder, of Cambridge, Mass., U.S.A., was elected an Honorary Fellow to fill the vacancy caused by the death of Prof. C. V. Riley.—The Secretary read a copy of a letter of condolence which he had written, by the direction of the Council, to the Entomological Society of France on the death of their President, M. E. L. Ragonot, and he also read the letter in reply from the Secretary of the Entomological Society of France.—Mr. R. Adkin exhibited a specimen of *Mesogona acetosellæ*, taken at Arlington, Sussex, in October 1895. It was stated that this was the first recorded capture of this species in Britain.—Mr. G. T. Porritt exhibited an example of *Halesus guttatipennis*, taken at Lye, Worcestershire, in November 1889. It was believed to be the third British example. Mr. Porritt also exhibited a series of *Mania typica*, showing a curious malformation in all the specimens. He stated that about one-third of a large brood had emerged in exactly the same form, having the wings only half developed, but with the markings clearly defined. Mr. Tutt and Mr. McLachlan referred to similar malformations in *Agrotis tritici* and *Hadena chenopodii*.—Mr. Goss read a communication from Mr. Sidney Crompton, of Salamanca, Tenerife, announcing the capture there by Mr. Hammerton of two specimens of *Diadema misippus*, a species of butterfly not previously recorded from Tenerife. Mr. Crompton said the specimens were in such fine condition that they must have been introduced into Tenerife in the larval or pupal state, and emerged there. Mr. Hampson, Prof. Meldola, and Mr. Osbert Salvin, F.R.S., made some remarks on the distribution of the species.—Mr. Champion read a paper entitled, "On the Heteromerous Coleoptera of St. Vincent, Grenada, and the Grenadines."—Mr. Kenneth J. Morton communicated a paper entitled, "New or Little Known Palæarctic Perlidæ."

Zoological Society, Nov. 19.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—A letter was read from Mr. J. H. Gurney, respecting a kingfisher (*Alcedo beavani*) which had been lately ascertained to be a permanent resident in some parts of Ceylon.—Mr. Sclater gave a short account of the principal animals he had noticed in the Jardin d'Acclimatation and Jardin des Plantes at Paris during a recent visit.—Mr. Sclater exhibited and made remarks upon the skin of a zebra from Nyasaland, obtained by Mr. R. Crawshay, and a remarkably fine pair of horns of a male Livingstone eland (*Oreas canna livingstonei*), which Mr. H. H. Johnston, C.B., had offered for the Society's acceptance. The animal had been shot by one of Mr. Johnston's hunters, in 1893, between Zomba and Lake Chilwa.—Colonel L. H. Irby exhibited and made remarks on two British-killed specimens of the greater bullfinch (*Pyrrhula major*).—Mr. W. T. Blanford, F.R.S., exhibited and made remarks on skins of *Capra sibirica* and of *Ovis ammon*, killed by Major Cumberland in the Altai mountains.—A communication was read from Mr. Swale Vincent, containing contributions to the comparative anatomy and histology of the supra-renal capsules. In the present paper Mr. Vincent described the naked-eye and microscopical anatomy of the supra-renal bodies in the different orders of fishes. He was inclined to the view that supra-renal bodies are present in all the Elasmobranchii, Holocephali, Ganoidei, and Teleostii, and probably also in the Dipnoi. The supra-renal bodies of fishes were in their essence "secreting glands," as the mammalian organ was now supposed to be. There was no relation whatever, in Mr. Vincent's opinion, between the supra-renals and the lymphatic head-kidney. In the great majority, at any rate, of Teleosteans they were both present in a well-developed condition.—Mr. Gerard W. Butler read a paper on the complete or partial suppression of the right lung in the Amphisbænidæ, and of the left lung in snakes and snake-like lizards and Amphibians. The author gave particulars as to the relative development of the right and left lungs in a large number of Amphisbænidæ and other snake-like lizards and snakes and limbless Amphibians,

which appeared to constitute a representative series, and found that, so far as the species on his lists were concerned, it was an invariable rule that in the Amphisbænidæ the right lung was the smaller, and usually rudimentary or absent, while in all other cases of inequality it was the left lung which was the smaller.—Mr. W. Saville Kent read some observations on the frilled lizard (*Chlamydosaurus kingi*) of Western Australia. After describing the peculiarities of this reptile, Mr. Saville Kent stated that he was inclined to regard it, if not as a surviving representative of the Dinosaurian reptilia, as, at any rate, a most interesting and anomalous lacertilian type that inherited its characteristic bipedal method of progression from that extinct group. Mr. Saville Kent's paper was copiously illustrated by photographs taken by him from life of *Chlamydosaurus* in its bipedal running and other characteristic attitudes, and also by specimens which had been mounted in strict accordance with these photographs.—Two communications were read from Dr. A. G. Butler, on a small collection of butterflies made by Consul Alfred Sharpe at Zomba, British Central Africa, and on a collection of Lepidoptera recently collected in Eastern Central Africa by Mr. G. F. Scott Elliot.—A communication was read from Mr. G. S. West, on the buccal glands and teeth of certain poisonous snakes. The author showed that in the Opisthoglyphous snakes the poison-gland is very variable both in form and extent, and that its duct opens into a cavity formed by muscular folds surrounding the grooved tooth. This opening is always towards the outer side of the grooved tooth, and situated either at its base or but a short distance from it, and the parts were shown to be so related that the loss of the tooth does not cause any injury to the duct. The reserve teeth were shown to be in no way connected with the duct until called upon to replace teeth that had been lost. The epithelium of the distal portion of the duct was shown to be of a secretory nature, the cells being mucus-secreting, similar to those forming the lining epithelium of the mouth. In the *Hydrophiinæ* the poison-gland was shown to be more or less free from the superior labial, and to consist of a large number of longitudinally-disposed tubules converging anteriorly towards a central poison-duct. There were two large poison-fangs situated almost side by side at the anterior extremity of the maxilla. The duct when approaching the region of the teeth became slightly sinuous and suddenly enlarged, enclosing a cavity into which there projected two muscular cushions, one in front of the base of each tooth, and it was through the vertical slit between these that the poisonous secretion passed from the duct to the grooves of the poison-teeth.—A communication was read from Mr. William H. Ashmead, containing a report upon the parasitic Hymenoptera of the Island of Grenada, comprising the families Cynipidæ, Ichneumonidæ, Braconidæ, and Proctotrypidæ. This paper enumerated as occurring in Grenada 183 species of the families named in the title, and described 128 of them as new. Of those previously known the majority had been recently described by Mr. Ashmead as found in the neighbouring island of St. Vincent. The Cynipidæ were all parasitic forms, there being apparently a total lack of any gall-making forms of the family in the island.

Geological Society, November 20.—Dr. Henry Woodward, F.R.S., President, in the chair.—The following communications were read:—"Additional Notes on the Tarns of Lakeland," by J. E. Marr, F.R.S. This paper was supplementary to one by the author published in the *Q. J. G. S.*, vol. li. (1895). It contained additional notes on Wateredbath Tarn, described Hard Tarn on Helvellyn, a pond of which the outlet had gradually been diverted from a course over screes to one over solid rock; Hayeswater, a lakelet referred to by Dr. H. R. Mill as in some respects intermediate between the mountain-tarns and the valley-lakes; and Angle Tarn, Patterdale, a good example of a plateau-tarn. In the discussion that followed, Dr. H. R. Mill said that as Mr. Marr had found every tarn that he examined to be held in by a barrier of drift, it seemed most likely that most, if not all, of the larger lakes would be found to owe their origin to the same cause. In this connection it was worth mentioning that Prof. W. M. Davis, of Harvard, considered, from the configuration of the larger lake-basins in the district, that they were produced in drift-blocked valleys.—"Notes on the Glacial Geology of Arctic Europe and its Islands. Part i. Kolguev Island," by Colonel H. W. Feilden, with a report on the erratic boulders from the Kolguev beds, by Prof. T. G. Bonney, F.R.S. Kolguev Island, about the size of Norfolk, was about 50 miles from Arctic Russia and about 130 miles south-west of the nearest part of Novaya Zemlya, with soundings not exceeding 30 fathoms between it and Russia, and probably not more than 75 fathoms between it and Novaya Zemlya. It was entirely composed of a vast accumulation of glacio-marine beds. The northern two-thirds of the island consisted of an elevated ridged area with a maximum height of 250 feet. The author had been furnished with notes by Mr. Trevor-Battye concerning the geology of this region. It was inferred from his observations that this elevated region was composed of beds of sand with erratic boulders not less than 80 feet deep, resting on clays—the "Kolguev clays." Mount Bolvana rose as a symmetrical cone above the tundra, detached from the northern plateau, pointing, in the opinion of the author, to the occurrence of marine erosion. The southern portion of the island was tundra, a dead flat of grass, bog, and peat-levels reaching to the sea; good sections of the Kolguev clays were exposed in the gullies traversing it near the sea on the western coast. In the vicinity of the Gobista river the Kolguev beds consisted of clays merging here and there into sands. They were charged with boulders often ice-scratched, indicating continuous deposition in a comparatively deep sea. The beds yielded many shells of arctic mollusca, such as *Saxicava arctica*, *Mya*, &c., apparently dispersed from top to bottom. The ice-pack had forced many fragments of semi-fossil wood on to the shore, no doubt worked up from a bed immediately below sea-level. No deposit was met with in Kolguev Island precisely similar to what is called "till" in Scotland, though there were many boulder clays in Britain which were in no measure superior in toughness to those of Kolguev; for instance, those of the Yorkshire coast, and the chalky boulder clays of Norfolk. It is suggestive that all the glacial deposits met with by the author in arctic and polar lands (except the terminal moraines now forming above sea-level) should be glacio-marine beds. Prof. Bonney, in his report, described the rocks brought home by the author. A discussion followed, in which Mr. Marr, Mr. Trevor-Battye, Mr. Boulger, Dr. G. J. Hinde, Dr. Gregory, and the Rev. Edwin Hill took part.

CAMBRIDGE.

Philosophical Society, November 11.—Prof. J. J. Thomson, President, in the chair.—The following communications were made:—A method of measuring the hysteresis of iron, by Mr. G. F. C. Searle. A bar of iron is placed in a solenoid, and the magnetising current flowing in the solenoid also passes through the fixed coils of an electrodynamometer. This current can be reversed. A secondary coil is wound on the iron, and the current induced in it by the variation in the magnetic induction passes also round the suspended coil of the electrodynamometer. Thus if H is the magnetic force due to the solenoid, and B is the magnetic induction in the iron, the current in the fixed coils is proportional to H, and the current in the suspended coil is proportional to dB/dt, provided that B changes so slowly that the effects due to self-induction in the secondary circuit are negligible. The couple experienced by the suspended coil at any time is proportional to HdB/dt, and thus the angular momentum acquired during a double reversal of the magnetising current is proportional to $\int HdB$ or to $4\pi \int HdI$, where I is the intensity of magnetisation. Thus the "throw" of the spot of light reflected from a mirror attached to the suspended coil is proportional to the energy lost in hysteresis during the double reversal. Experiments were shown to illustrate the manner in which the method could be applied to investigate the effects of strain and temperature upon the hysteresis in iron.—The form of cubic surfaces containing twenty-seven real straight lines, by Mr. W. H. Blythe. The paper was illustrated by two plaster models. The first represented the general case of a cubic surface having twenty-seven real straight lines, the position of the lines being shown by threads. The second was a rough model of the special form having a tangent plane at infinity, which contains three of the lines. It is constructed to show the position of the remaining twenty-four straight lines, which form a symmetrical system.—Expansion produced by the electric discharge, by Miss Martin. At the suggestion of Prof. Thomson, the experiments of Meissner on the expansion of gases by the electric discharge were repeated by Miss Martin. After some preliminary experiments, in which the results obtained differed from those of Meissner, new apparatus was set up, an exact copy of Meissner's, consisting of an ozone generator with a sulphuric acid pressure-gauge attached; the two tinfoil coats of the generator were connected with the terminals of an electrical machine. In Meissner's original experiments it was

thought that the precaution of never separating the terminals of the electrical machine further than by a small fraction of the distance between the coats of the generator would ensure the absence of discharge between the coats; and in the conditions adopted, Meissner observed that when discharge took place by the passage of a spark between the terminals, there was a temporary increase of pressure; the effect being most marked in the case of CO_2, and least marked in H. In Miss Martin's repetition of the experiments, the generator was put in a dark box, provision being made to let the gauge and the space between the coats of the generator be seen. It was then established that in no case could any deflection of the gauge be seen, except when luminosity could be detected in the generator. It was further observed that when the discharge passed through CO_2 a permanent contraction was produced. The experiments have been repeated by Prof. Thomson, and he finds that if wet CO_2 is used, the effect is more marked; but if carefully dried CO_2 is used, no contraction is produced.

PARIS.

Academy of Sciences, December 2.—M. A. Cornu in the chair.—On the extension of the ideas of Galois to the theory of differential equations, by M. Émile Picard.—Remark on a memoir, by M. Jaumann, entitled, "Longitudinal Light." A note by M. H. Poincaré. The author derives equations, from those found by M. Jaumann, which indicate properties for cathode rays not agreeing with facts, and hence considers that modifications are needed in the hypotheses put forward in the memoir.—On the presence of sodium in aluminium prepared by electrolysis, by M. Henri Moissan. It is shown that electrolytic aluminium contains in general from 0·1 to 0·3 per cent. of sodium, and that the presence of this impurity renders the metal easily attacked by water. Aluminium should always be used alone and pure, as it readily forms electric couples with every other metal, and is then easily attacked by water.—On the origin of argon and of helium in gases disengaged by certain sulphurous waters, by MM. L. Troost and L. Ouvrard. It is shown that, though argon is generally present in waters, helium is only found in certain mineral waters, and does not probably owe its origin to the atmosphere, but to the rocks through which the waters have percolated. M. Bouchard added some remarks on the therapeutic value of helium and argon, and supported the view that these gases have no action on the economy, but admitted that the metals present in helium containing minerals might have medical action when present in minimal amounts.—Structure of the mesenteric ganglia of the pig, by M. L. Ranvier.—Observations on Perrine's comet (16 November, 1895) made with the great equatorial at Bordeaux Observatory by MM. G. Rayet and L. Picart. Note by M. G. Rayet.—M. Ch. V. Zenger, in a note entitled "Studies in molecular physics," sets forth a very simple relation between the density and specific heat of chemical elements, and indicates a new view of the genesis of the elements.—Observations of Swift's comet (1895, August 20) made with the great telescope, and of Perrine's comet (1895, November 16) made with the 0·25m. equatorial at Toulouse Observatory, by M. Rossard.—Note on the construction of the calendar, by M. A. Auric.—On Lamé's equation, by M. G. Floquet.—On the extension of Cauchy's method to systems of equations to the derived partials of any order whatever, by M. J. Beudon.—On the functions of two real variables and on the motion of an arbitrary function, by M. Émile Borel.—On orthogonal systems, by M. Paul Adam.—On a new determination of the ratio between the electrostatic and electromagnetic units, by M. D. Hurmuzescu. The value found gives

$$v = 3{\cdot}0005 \times 10^{10} \text{ to } 3{\cdot}0020 \times 10^{10}.$$

—Relation between the intensity of light and the chemical decomposition which it produces; experiments with mixtures of ferric chloride and oxalic acid, by M. Georges Lemoine. The chemical decomposition of a mixture of ferric chloride and oxalic acid is proportional to the luminous intensity.—On the presence of argon and helium in a natural source of nitrogen, by M. Ch. Moureu.—Experimental determination of the agglutinating power of oils, by M. Louis Campredon.—On a chromium amalgam and some properties of metallic chromium, by M. J. Férée.—On a method of synthesis of complex amides, by M. Albert Colson.—New examples of the superposition of optical effects of asymmetric carbon atoms, by MM. Ph. A. Guye and Ch. Goudet.—On a zoological exploration of Corsica, by M. Louis Roule.—On the anatomy and systematic position of compound Ascidians of the genus *Sigillina*, Sav., by M. Maurice Caullery.—On the accumulation of sugar in beetroots, by M. L. Maquenne.—The pliocene and quaternary glaciers of Auvergne, by M. Marcellin Boule.—On the geology and "tectonique" of the Central Caucasus, by M. E. Fournier.—On two new forms of quartz, by M. P. Termier.—On the effects of the tropical revolutions of the sun and of the moon on the barometric pressure, by M. P. Garrigou-Lagrange.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Congrès de l'Atmosphère 1894, Compte Rendu (Anvers).—Introduction to the Study of Fungi: Dr. M. C. Cooke (Black).—Mensuration for the Use of Schools, &c.: Rev. A. D. Clarke (Rivington).—Modern Microscopy: M. I. Cross and M. J. Cole, 2nd edition (Baillière).—Practical Inorganic Chemistry: Dr. G. S. Turpin (Macmillan).—The Pterophorina of Britain: J. W. Tutt (Hartlepool, Robson).—Elementary Algebra: J. W. Welsford and C. H. P. Mayo (Longmans).—University College, Nottingham, Calendar 1895-96 (Nottingham, Sands).—Compensacion de Declinaciones Magnéticas en la Peninsula Ibérica: Don R. P. de Figueroa (Madrid).—Lehrbuch der Entwicklungsgeschichte des Menschen und der Wirbethiere, Dr. O. Hertwig, Fünfte Auflage (Jena, Fischer).—Principles of Metallurgy: A. H. Hiorns (Macmillan).—Macmillan's Geography Readers, Book vii. (Macmillan).—Elements of Geometry: G. C. Edwards (Macmillan).—Essays in Taxation: Prof. E. R. A. Seligman (Macmillan).—Regeneration, a Reply to Max Nordau (Constable).—The Key of the Pacific, the Nicaragua Canal: A. R. Colquhoun (Constable).—Service Chemistry: Prof. V. B. Lewes, 2nd edition (Whittingham).—Physical Measurements: F. C. Weedon (Gill).—Imperial University of Japan, Calendar 1894-95 (Tōkyō).—Handbuch der Mineralchemie: Dr. C. F. Rammelsberg, Zweites Ergänzungsheft zur Zweiten Auflage (Leipzig, Engelmann).—Kurzes Handbuch der Kohlenhydrate: Dr. B. Tollens, Zweiter Band (Berlin, Trewendt).

PAMPHLETS.—Ethnography of the Mullet, Inishkea Islands and Portacloy, Co. Mayo: Dr. C. R. Browne (Dublin).—On Memory and the Specific Energies of the Nervous System: Prof. E. Hering (Open Court Publishing Company).—Spiritual Truth and Common Sense: B. Hodgson (Birmingham, Cornish).—On the Localisation of the Foramina at the Base of the Skull: Prof. E. Fawcett (Bristol, Arrowsmith).

SERIALS.—Botanische Jahrbücher. &c., Zweiundzwanzigster Band 1, Heft (Leipzig, Engelmann).—Zeitschrift für Physikalische Chemie, xviii. Band, 3 Heft (Leipzig, Engelmann).—History of Mankind: F. CONTENTS.

THURSDAY DECEMBER 19, 1895.

THE ORIGIN OF PLANT STRUCTURES.

The Origin of Plant Structures by Self-adaptation to the Environment. By the Rev. G. Henslow, M.A., F.L.S., &c. International Scientific Series. Pp. xii + 256. (London: Kegan Paul, 1895.)

THE present work may be regarded as the second part of the "Origin of Floral Structures," published by the same author in 1888. In that volume Prof. Henslow propounded his Neo-Lamarckian view, that all differences of colour, shape, and size of floral organs have been directly caused by the influences surrounding the plant. The visits of insects, with their constant thrusts and probings, have produced, as a direct result, all the variety of the phanerogam flower.

In the present volume, the same proposition is extended to the vegetative organs of plants, of which the efficient cause of diversity, whether of external or internal morphology, is to be sought in changes in the conditions of life. In this way the author makes studies of the following special cases:—Desert plants, Arctic and Alpine plants, maritime and saline plants, phanerogamous aquatics, subterranean structures, climbing stems and leaves. From a careful analysis of the biological peculiarities of these forms, Prof. Henslow claims to draw strong support for his views.

The Darwinian hypothesis assumes, in the offspring, constant minute variations in all directions from the parent type: those variations that are of service to the plant in its struggle for existence, are perpetuated and increased by natural selection and heredity. Prof. Henslow denies the existence of natural selection altogether: variations in nature, according to him, are never indefinite, but always definite, and, being induced by the change of environment, and the responsive action of protoplasm, they are always in the direction of adapting a plant to its surroundings.

The test of a theory lies in the wideness of its application; and herein exists the great beauty of Darwin's hypothesis. After all these years of severest criticism, no definite proofs have been urged against it; and the best that Prof. Henslow can do is to offer a substitute which, to his mind, furnishes an easier solution to the difficulties of certain selected cases.

Whatever may be the opinion of others, the author himself is sure of his ground. The introduction opens with these words: "Natural Selection plays no part in the Origin of Species." This dictum is not likely to be accepted by the general scientific world without very strong support. The imputation of narrowness of field in Darwin's observations is hardly in good taste, while such headings as "Darwin's Fundamental Error" predispose the mind to a critical attitude.

It is usually agreed that, from the nature of the case, a definite proof of the action of natural selection is difficult, if not impossible, in the present state of our knowledge. This the author of the present volume concedes, and at the same time puts forth arguments against the probability of such proofs being forthcoming. With considerable skill, if with rather superfluous detail, he discusses the manner in which the environment impresses itself upon the anatomy of plants. Of the *inheritance* of such acquired characters there is no proof at all. We are offered instead the "argument of coincidences" and the "cumulative evidence of probabilities, which amounts to a moral conviction." Clearly, before rejecting a well-established and widely applicable hypothesis, something more tangible is required.

In each section of the present volume, Prof. Henslow presents the reader with an interesting picture of the biology of a group of plants. The descriptions would, we think, be clearer if the writer had condensed his quotations somewhat. As it is, the interpolation in the text of long passages—frequently in French—mars the simplicity.

We emphasise this point because of the character of the author's reasoning. He is an exceedingly plausible and persevering casuist; and it is, on that account, all the more desirable that the reader should retain a clear impression of the course of the argument.

To take a specimen of the author's method. In speaking of the frequent hairiness of desert plants, as contrasted with those more favourably situated, Prof. Henslow quotes Mer, to the effect that "*cæteris paribus* hairs are the result of localised extra nourishment." This, he points out, was long ago suggested by Aug. Pyr. de Candolle as the cause of the hairiness of the barren inflorescence of *Rhus Cotinus*, where the nutrition, which would normally be applied to the formation of flowers and seeds, finds a new outlet. So with the hairy filaments of *Verbascum* and other flowers where some of the anthers are barren or suppressed; also, as Masters has pointed out, the hairy outgrowths in many galls.

The "localised extra nourishment" of desert plants the author accounts for in the following manner. There is a characteristic diminution in the size of the leaves in desert plants, due principally to a decrease in the parenchymatous tissues; hence, it is argued, there is an arrested food supply which, "by a compensating process," is used up in the formation of hairs.

To take another instance: the rapid maturing and seeding of plants, in regions of short summer, is traced to the changes which take place in the reserve materials during the low temperatures of the long winter preceding, just as frosted potatoes shoot out quickly in the spring.

We are not sure that, in these attempts to define the exact mode of "the responsive action of protoplasm," the author does not deprive it of more of its independent and unexplained reactions than is justified by our present knowledge.

In a word, each argument, although composed of a chain of neat and plausible propositions, lacks coherence and, somehow, fails to carry conviction. In each change of environment, the protoplasm is, so to speak, induced, by a kind of internal conjuring, to present the very modification of structure which will be of service to the plant under the altered conditions.

It has been pointed out that only isolated cases have been dealt with in this volume; but, for the hypothesis to be acceptable, it must be widely applicable. We should like to learn how the beautifully fashioned hooks

of the seeds of *Martynia* have been formed, or the delicate tracery of the pappus of *Tragopogon*, the insectivorous glands of *Drosera*, the roots of *Acanthorrhiza* which grow upwards and become a thorny hedge around the young plant, or the profusion of thorns upon the palms of moist tropical forests. Although fraught with difficulties, the Darwinian theory embraces all such cases; while that defended by the author requires a new line of argument in each separate instance.

Prof. Henslow is rich in expedients, and is a fearless theoriser. He regards the opposite or decussate arrangement of leaves as the primitive, because of the position of the cotyledons; the sheathing base of *Monocotyledons* and *Umbellifers* is a mark of degeneracy; the heterophylly of *Juniperus* is caused by a variation in the amount of nutriment at the plant's disposal. He suggests that the enlarged watery, subterranean parts of desert plants may be due to the blistering action of the hot sand, and that the thickened cuticle of plants in dry climates may be formed or aided by a deoxidation of chlorophyll by excessive light. Lastly, he explains the fact, observed by Volkens, that the stomata of desert plants are frequently closed in the day and open at night, by a reversal of the ordinary reactions of the guard cells to turgescence. "Perhaps the arrested moisture, due to the check to transpiration, may cause turgescence by day, which closes the slit, while its cessation at night brings about a relaxation."

We confess that Prof. Henslow's views on geotropism are puzzling and disappointing. He denies the existence of negative geotropism; and bases his argument, curiously enough, upon Knight's well-known wheel experiment. Here he discovers a *centripetal pulling* force which causes the stem apex to grow towards the centre of the rotating wheel, and at the same time a *centrifugal pulling* force which causes the root to grow outwards. "Each end of the plant is therefore subjected to what might be called an accelerating 'pulling' force." A moment's consideration will show that there is no such *centripetal pulling* force acting upon the free stem-apex. Prof. Henslow seems to lose sight of the fact that the action of gravity upon parts of plants is directive rather than purely mechanical.

Further, it is not clear why gravity ceases to act upon the apex of *Ranunculus heterophyllus* because it is immersed in water (p. 201)!

There are many points which will exercise the morphologist. Why are the first leaves of water plants regarded as phyllodes? We hardly agree with Prof. Henslow's ideas on the interchangeability of stems and roots in nature, although each may arise from the other endogenously.

Then again, it is difficult to follow the author's description of the vascular system of water plants on pages 145–7. We gather that he regards "spirals" as the only true "tracheæ"; and "vessels" appear to have quite a different meaning. The following is far from clear: "In aquatics the punctated vessels may closely simulate punctated fibres, the chief differences being in the lessened diameter of the latter, and the more or less oblique position of the septa. Then these pass into thin-walled fibres of the same shape, and finally become 'fibrous cells,' when they may contain starch."

We have read the volume with great pleasure, both because of the mass of interesting details of plant biology, and the ingenious piecing together of evidence; nevertheless, we do not think that Prof. Henslow's attempts to reconstitute the theory of evolution are altogether successful. C. A. BARBER.

SOLUTION AND ELECTROLYSIS.

Solution and Electrolysis. By W. C. Dampier Whetham, M.A. (Cambridge: The University Press, 1895.)

UP till the beginning of the present year the English reader had practically only two text-books to guide him in getting some idea of the scope and importance of the Newer Theory of solutions. These were "Solutions," a translation of certain parts of Ostwald's Lehrbuch, and "Outlines of General Chemistry," by the same author. The former gave but an imperfect account of the subject, as it excluded the electrical properties of solutions, and thus the mass of material which groups itself around the hypothesis of electrolytic dissociation; while the latter, although giving a general survey of the theory, dealt with it in but a superficial manner. To these was added, early in the present year, Nernst's "Theoretical Chemistry," and in this book is to be found the best description in English of the present condition of the theory; for although the description is by no means rich in records of actual observations, yet, on account of the neat methods used in dealing with the theory of individual questions, and the comprehensive mode of attacking the entire subject, it is worthy of the attention of all students of physical chemistry.

The book under notice gives a much more detailed survey of the theory as a whole than that found in Ostwald's "Outlines." The mode of treatment is, however, less thorough than that in Ostwald's "Solutions," and has little resemblance to the compact and orderly method used by Nernst.

In his preface the author states that a considerable part of the first six chapters is taken from Ostwald's Lehrbuch, and this is unmistakably evident on reading them through. They deal with solubility, the different kinds of solutions, diffusion and osmotic pressure, freezing-points, and vapour-pressures. The remaining five chapters have much greater claims to originality, and are devoted to the electrical properties of solutions—Faraday's laws, polarisation, the theory of the voltaic cell, the migration and velocity of the ions, electric conductivity and its correlation with other properties, and theories of electrolysis.

The student familiar with the elements of physics and chemistry will have little difficulty in following the information supplied. The author has, in particular, to be thanked for setting out at length the more important applications of thermodynamics to solutions, as these are often a source of worry to the beginner. Many indications are also given of attention to points which are often scantily treated, as in the case of the theory of diffusion, the meaning of osmotic pressure, the theory of the voltaic cell, &c. On the other hand, the treatment of solutions in gases, associated solutions, Beckmann's molecular weight apparatus, &c., is extremely superficial. There-

are also certain points to which attention must be drawn, in view of future editions of the book.

When dealing with plasmolysis (p. 37), the author omits to state that the animal or vegetable cells used must contain living protoplasm, and the reader is led to infer that artificially-coloured, instead of naturally-coloured cells are employed for plasmolytic observations. Although certain stains are known which are not immediately fatal to living cells, there is no record of their use in plasmolytic experiments. It is also made to appear that red blood corpuscles contain a semi-permeable membrane, despite the conclusive observations of Hamburger to the contrary. In connection with this subject, it is misleading to state (p. 38) that De Vries "established the most important generalisation" that solutions of the same molecular concentration are isotonic, for inasmuch as by far the greater number of his solutions were electrolytic, his results clearly contradict this statement. On p. 34, the credit of preparing semi-permeable membranes is given to Pfeffer, whereas M. Traube first described their preparation and properties. As regards the more general treatment of the first section, it is noteworthy that although the solubility of mixed substances is to some extent discussed, no notice is taken of the work of Roozeboom, and Gibbs' phase-rules, which apply to all cases of heterogeneous equilibrium in solution, are not even mentioned.

In the section on electrolysis, some inkling might have been given of the wide field opened up for the verification of the ionic hypothesis by its application to the operations of analytical chemistry. Among smaller points, it may be noted that, on p. 128, potassium platinichloride should be sodium platinichloride, and in a somewhat vague paragraph, on p. 164, we read that the introduction of oxygen, sulphur, or a halogen, which raises the affinity of a weak acid, "has no effect on the affinity of these strong acids." Since the strong acids quoted by the author are hydrochloric, nitric, &c., the student may be pardoned if he is puzzled to understand how the introduction is to be brought about, or what acids would result if it were possible.

A novel feature in a book of this kind is an attempt made by the author to reconcile the Hydrate Theory with the Newer Theory of solutions. Of course it has all along been apparent that the latter does not preclude combination between solvent and dissolved substance. What the upholders of the newer theory assert, however, is that at the present time there is no definite evidence that, in general, such combination exists. An attempt to reconcile the two views should therefore involve a careful study of the experimental data in favour of combination. It is for this reason unfortunate that the author gives but a very brief statement of the results of the extensive work of Pickering in this field.

As an appendix to the book is given part of the list of the conductivity, migration, and fluidity data of solutions compiled by Fitzpatrick for the British Association Report of 1893. For the sake of chemical readers it is to be regretted that most of Ostwald's observations on the conductivity of organic substances have been omitted, since it is in the case of such substances that the close connection between the electrolytic properties of solutions and the chemical nature of the dissolved substances can be most conveniently traced. J. W. RODGER.

THE THEORY OF ALGEBRAIC FORMS.

An Introduction to the Algebra of Quantics. By E. B. Elliott, M.A., F.R.S. Pp. xiv. + 424. (Oxford: Clarendon Press, 1895.)

THE history of the theory of algebraic forms gives a striking example of the fact that the germ of a mathematical doctrine may remain dormant for a long period, and then suddenly develop in a most surprising way. The principles of the calculus of forms are to be found in the arithmetical works of Lagrange, Gauss, and Eisenstein; but the great expansion of the theory, with which we are now so familiar, practically dates from the publication of the papers of Boole, Cayley, and Sylvester, about fifty years ago.

It is well known that the theory of forms has advanced upon two distinct lines: one method being derived mainly from the differential equation of sources, supplemented by generating functions and the theory of equations; the other, from the symbolical representation of a quantic, invented by Aronhold, and applied with such power by Clebsch and Gordan. Until quite lately, the symbolical method might not unjustly claim to be superior in respect of organic unity, as it must still be admitted to be in compactness and geometrical suggestiveness; but the other method has now undergone a remarkable transformation at the hands of Hammond, MacMahon, Hilbert, and others, and has led to results of the highest interest and value, which the symbolical calculus could not easily or naturally supply.

With the exception of three pages, devoted principally to Cayley's hyperdeterminant notation, Prof. Elliott does not refer to the symbolical method. With his reasons for not using it we must reluctantly acquiesce. It is quite true, as he says, that a mere outline of the method would have been worse than useless; and by omitting it altogether, he has been enabled to give a very lucid and thorough account of the subject from one consistent point of view, without that excessive condensation which is so often a defect rather than a merit.

It is not necessary to say much of the earlier chapters, except that, like the rest of the book, they are very clear and pleasant to read; in particular, the proof that every covariant of a covariant is a covariant of the original form is easier to follow than that given by Salmon. It is when we come to chapters vi. and vii., which deal with seminvariants and their annihilators, that the influence of recent discoveries begins to be felt. Thus the notions of *excess* and *extent* are introduced, and the annihilators of invariants and covariants of systems of quantics are indicated.

Chapter viii. discusses generating functions, and is a very good introduction to this part of the subject. It does not profess to be exhaustive; and it is perhaps as well that the author has refrained from giving the detailed reduction of the generating functions for forms higher than the quartic. This would have taken up a good deal of space; and the full discussion for the lower forms, which is given, is quite enough to illustrate the general procedure. The results for the quintic are also stated, and references are given to the memoirs of Sylvester and Franklin, which ought to be easily understood by any one who has mastered this chapter.

Another very interesting chapter follows. This contains Hilbert's proof of Gordan's celebrated theorem, that the number of irreducible concomitants is finite. Compared with Gordan's original proof, this is simplicity itself; and it is unlikely that the demonstration can be essentially improved upon in this respect, although no doubt some simplification in detail may be effected.

Chapters x. and xi. are also well brought up to date. They deal with protomorphs and perpetuants, and the connection of seminvariants with non-unitary symmetric functions. It is needless to say that they are based principally on the researches of MacMahon and Hammond. The deduction of the annihilator of non-unitary symmetric functions of the quantic

$$b_0 x^p + \frac{b_1}{1!} x^{p-1} + \frac{b_2}{2!} x^{p-2} + \ldots + \frac{b_p}{p!}$$

seems rather artificial, as it is made to depend upon the transformation

$$-\frac{\partial}{\partial s_1} = b_0 \frac{\partial}{\partial b_1} + 2b_1 \frac{\partial}{\partial b_2} + \ldots \; pb_{p-1} \frac{\partial}{\partial b_p}$$

But this is a small matter, and the chapters are full of interest. One remarkable novelty is a differential operator which annihilates any rational integral function whatever of the coefficients of a finite quantic. Here is, indeed, a universal solvent. It should be added that the examples at the end of chapter xi. give a synopsis of Stroh's verification of MacMahon's brilliant conjecture that the generating function for perpetuants of degree i is

$$\frac{x^{2^{i-1}} - 1}{(1 - x^2)(1 - x^3) \ldots (1 - x^i)} \ldots (i > 2)$$

The remaining chapters (xii.–xvi.) treat of canonical forms, the binary quintic and sextic, systems of binary quantics, orthogonal invariants, and the ternary quadratic and cubic. The chapter on the quintic and sextic does not go into detail, but gives complete lists of the concomitants, and in particular the explicit forms (supplied by Mr. Hammond) for the quintic $(a, b, 0, 0, e, f)(x, y)^5$. The other chapters do not seem to call for special remark; suffice it to say that they maintain the high standard of those which precede them.

Prof. Elliott states in his preface that the book is an expansion of a course of lectures delivered annually for some years past at Oxford. To this fact, no doubt, may be attributed, in some measure, the lucidity and symmetry of the treatise. Another good feature, perhaps due to the same cause, is the occasional statement of what a theorem does *not* imply. To the well-informed reader this may seem superfluous, but it is by no means so in the case of a learner, who not infrequently reads into a theorem a degree of generality which it does not really contain.

To return to the symbolical method of Clebsch and Aronhold. Prof. Elliott admits that an English work on this calculus is a desideratum; will he not be persuaded to supply this want himself? It would be a great boon to have an English book something after the kind of the Clebsch-Lindemann "Geometrie," including, at least, the theory of plane quadratic and cubic curves, and of surfaces of the second order, with perhaps an introduction to the theory of cubic surfaces. This is, no doubt, a heavy task, but it is well worth attempting; the theory of forms is infinitely more interesting in its geometrical applications than as a mere branch of analysis, and it is here, above all, that the power of the symbolic method shows itself. Such a work would do much to avert the danger of divorcing the theory of forms from analytical geometry; a danger which is encouraged by the present regulations of the mathematical tripos, which place these cognate subjects in two different divisions.

G. B. M.

SURFACE-COLOURS.

Die Oberflächen- oder Schiller-Farben. Von Dr. B. Walter. 1 vol., with 8 woodcuts and 1 plate. Pp. vi. + 122. (Braunschweig: F. Vieweg und Sohn, 1895.)

THIS work is primarily addressed to zoologists, mineralogists, and chemists, appealing in only a subordinate measure to physicists. On this account the mathematical developments most desirable for the physicist are reserved for appendices, while the text itself contains only such matter as is vital to the theory of surface-colours, together with very simple and well-established formulæ given without proof.

The importance to the first-named classes of an acquaintance with the physical basis of these colours immediately appears, says the author, from the facts that, on the one hand, to this class of colours belong the tints of many butterflies and birds, and also those of a series of crystals exhibiting the most gorgeous natural phenomena; and on the other hand, the technologist, if he desires artistically to imitate these colours, must naturally, first of all, obtain a true insight into their manner of production. Now, although this treatise contains no startling additions to our physical knowledge of surface-colours, it may yet be expected to render a most acceptable service to this branch of physics, since in many minds there still linger hazy, or even discordant, conceptions of these colours, and until now no work seems to have appeared devoting to the subject even any approach to an exhaustive treatment.

Of the experiments, which form the basis of the calculations and statements contained in this book, those which are new have been carried out by the author in the State Physical Laboratory at Hamburg.

The first chapter is a brief introduction to the subject of the work. The second and third chapters treat of the surface-colours of colourless materials and of metals respectively. In the fourth chapter, embracing about a third of the entire treatise, the author discusses the dichroic substances proper; solid fuchsine and diamond green, also solutions of these, and fluorescein solution being specially dealt with. This chapter is unusually rich in experimental results. It is pointed out that the body-colour and the surface-colour are only approximately complementary, and are not exactly so, as stated in Haidinger's law. We have also here the following important statement: "The coefficient of reflexion of a particular ray from a given substance depends not only upon the absorption coefficient of the substance for that ray, but also upon its refractive index for the ray in question, the relative importance of these two factors varying with circumstances, so that in the case of the feebly-absorbed rays of coloured substances the refractive index is prac-

tically the sole factor in determining the intensity of the reflected light."

In chapter v. the distinguishing characteristics which separate surface-colours from other classes of colours are noted. The following kinds of colours are treated: (1) body-colours; (2) the colours of turbid media; (3) the prismatic dispersion colours; (4) the spectral colours of the diffraction grating; and (5) the colours of thin plates. With reference to the latter, the author calls attention to the fact that if one changes the polarisation of the incident light used in producing the colours of thin plates, the result is simply a change in the *intensity* of the colours, no change in their *tint* being thereby caused; whereas with surface-colours proper, under the same circumstances, *both intensity and tint* are thereby changed. The body of the work concludes with a sixth chapter, dealing with the occurrence of surface-colours in the animal and mineral kingdoms.

E. H. B.

OUR BOOK SHELF.

Studies from the Biological Laboratories of the Owens College. Vols. i. (pp. 328), ii. (pp. 268), iii. (pp. 286), 1886, 1890, and 1895. (Manchester: Cornish.)

THERE is growing up among us a habit of collecting and publishing reprints of memoirs as "Studies" from this laboratory or from that; and a very excellent habit it appears to us to be. We have known for some years the "Studies from the Morphological Laboratory" of Cambridge; we have seen "Reports" from the Physiological Laboratory of University College, London; "Transactions" from Dundee, edited by Prof. D'Arcy Thompson, and quite recently we referred to the youngest of such publications, viz. the "Linacre Reports" of the zoological work at Oxford, edited by Prof. Ray Lankester.

All such collections serve the useful purpose of indicating the character and amount of work carried out at the various important teaching institutions of the kingdom, and of emphasising the fact that the best teaching work is performed by those engaged in research. It may be objected that the memoirs contained in such "Studies" can be found elsewhere. This is, in general, true; but, nevertheless, such collections help to associate more readily in our minds the workers with their masters and the institutions to which they are attached; and oftentimes it brings together, in a compact form, a series of contributions undertaken with some special object, by different workers it may be, or by one man.

The first volume of these "Studies" from Manchester was published in 1886, the second in 1890, the third during the present year; the last is under the editorship of Dr. Sydney Hickson, the two former by the late Professor. These volumes contain several valuable memoirs, some of which are already classical, such as Marshall's "Segmental Value of the Cranial Nerves," Beard's account of the Branchial Sense-organs, and Melland's contribution to the Histology of Striated Muscle; and to these will have to be added, no doubt, the researches of Marshall and Bles on the Development of the Vascular System, and of the Kidneys in the Frog, Robinson's observations on the Development of the Optic Nerve, Paterson's account of the Origin of the Nerve-plexus of the Limbs, and other embryological papers undertaken at the suggestion of the late Professor.

In addition to these developmental memoirs, those by Fowler on the anatomy of Corals, and by Garstang and by Gamble on the Fauna of the British Coasts, have a permanent value. In the last volume, Milnes Marshall's interesting "Address" at the British Association, dealing with "Recapitulation in Ontogeny," is reprinted.

The absence of botanical research in the later volumes is the more noticeable, as Prof. Marshall Ward contributed to the first volume. We hope that botanical research is not dead in Manchester.

Palæontology is represented by Dr. Hurst's account of *Archæopteryx.*

The quality and extent of ten years' work brought together in these three volumes, bear witness to the energy and influence of the late Beyer Professor; and we may echo Prof. Hickson's prefatory remark, that "his influence will long be felt in the writings of his pupils and successors."

Studies in Economics. By William Smart, M.A., LL.D. Pp. 341. (London: Macmillan and Co., 1895.)

DR. SMART is favourably known in the economic world by his admirable translations of the writings of the Austrian school; and in these "Studies" the characteristic doctrines of that school furnish no small part of the theoretic apparatus. The exclusive emphasis laid on that side of the theory of value, the elaboration of which is connected in this country chiefly with the name of Jevons—the side of demand, that is, with its controlling factor of marginal utility—is faithfully reproduced by Dr. Smart; and, like the teachers, whose disciple he frankly acknowledges himself to be, he is disposed to treat as "secondary" and "derivative" that influence of cost of production as governing supply, and, through supply, determining value, to which the older English economists, such as Ricardo and Mill, assigned predominant stress. He describes the Austrian theory as the "current" and "dominant" theory; and, while he sometimes accords a hesitating recognition to conceptions which seem to conflict with this exclusive emphasis, his attitude even here appears to be in reality one of doubtful acceptance rather than hearty concurrence. To the writer of this review the later, like the older emphasis, seems mistaken; and the comprehensive attitude of Prof. Marshall, who treats the two sides of supply and demand as mutually determining, appears to be more closely in accord with the facts; and in this impression he is strengthened by the difficulties encountered by Dr. Smart in some of these "Studies" from an unwillingness to allow to cost of production a coordinate influence with that of marginal utility in determining value. On Prof. Marshall's hypothesis the facts seem to fall naturally into their place, but by the Austrians and by Dr. Smart they appear to be forced artificially into a strained position. To this theoretic equipment Dr. Smart has added the valuable qualification of a first-hand acquaintance with the facts of business life; and the advantage of this intimate knowledge is evident in many parts of his book. It consists of three main sections, one devoted to studies in wages, the second to studies in currency, and the third to studies in consumption. Of these the first seems to us the most valuable; and the reason consists in the fact that Dr. Smart's business experience brings a strong admixture of practical sagacity to bear on such matters of concrete interest as a "living wage," the "sliding scale," and "women's wages." He owns in his preface to a proneness, not unnatural in a business man, to "lose himself in the fallacy of the particular instance"; and we are not sure that he has in the course of these "Studies" always avoided this fallacy. But he never fails to be interesting and suggestive, and he is, with rare exceptions, uniformly lucid; and these are qualities as admirable as they are rare in combination. The economic student and—in a more especial degree—the practical man, will find material for profitable reflection in the careful perusal of these interesting "Studies."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Intensity and Quantity of Sunheat at Different Zones.

THE following figures may interest readers of NATURE. They give the relative summer and winter *intensities* of sunheat for every five degrees of latitude, *i.e.* the sunheat per square foot—and also the relative *total quantities* of heat received at the zones extending from 0°–5°, 5°–15°, &c.

Latitude	0°	5°	10°	15°	20°	25°	30°	35°	40°	45°
Summer Intensity	943	971	997	1016	1026	1030	1026	1016	997	973
Winter Intensity	961	915	866	808	752	694	634	569	498	423

Latitude	50°	55°	60°	65°	70°	75°	80°	85°	90°
Summer Intensity	947	909	868	840	821	806	793	780	766
Winter Intensity	345	269	197	135	79	40	18	5	0

Zone	0-5°	5-15°	15-25°	25-35°	35-45°	45-55°	55-65°	65-75°	75-85°
Summer Heat	478	987	964	886	764	612	434	286	84
Winter Heat	469	857	707	550	331	269	100	27	9

The figures are not guaranteed as accurate to the last place, but that place is included so that the totals may be fairly correct when we take the total sunheat over several zones. Thus we get the summer and winter sunheat up to latitude 30° in the ratio of 30 to 23, while from the cap from 30° to the pole the quantities are 25 to 10, on the same scale. Again the summer and winter proportions from 0°–45° and 45°–90° are 43 to 29 and 12 to 4 respectively.

The proportion of the summer and winter sunheats received by the entire hemisphere is obtained as 55 to 33, the unit being the same as before. That these two are almost exactly in the ratio of Ball's and Weiner's numbers, 63 to 37, may be regarded as a sufficient check on the accuracy of the figures, which were calculated separately. E. P. CULVERWELL.

Trinity College, Dublin, November 25.

The Discovery of the Anti-Toxin of Snake-Poison.

IN reference to the statements contained in Prof. Ray Lankester's letter in your issue of December 12, I have to point out that no claim of priority has ever been advanced by me.

Hitherto my communications have been of the nature of preliminary statements, and in such communications it is neither possible to enter into details of the work done by others on the same subject, nor usual to attempt to do so.

On each occasion in which I have described the results of my experiments, I have briefly referred to all previous workers on the subject, in so far as they were known to me; and, in particular, I have definitely mentioned, or otherwise drawn attention to the circumstance that, before I had been able to do so, M. Calmette had published evidence showing that animals could be immunised against snake-venom, and that the blood-serum of those animals possesses antidotal properties.

At the same time, the work done by me was absolutely independent in its conception. It was originated several years ago, and has been carried out on a plan and with aims which were formed independently of the work of any other experimenter. That part of it which has as yet been described in the published abstracts had for the most part been completed before M. Calmette's paper announcing successful immunisation had come to my knowledge. I have rarely had occasion to consult Pasteur's *Annales*, and thus it happened that M. Calmette's paper was noticed only when the literature of a different and purely bacteriological subject was being collected for me. As to the articles in the *Contemporary Review*, I have not seen them, nor did I know of their existence until they were mentioned by Prof. Lankester. THOMAS R. FRASER.

Edinburgh, December 16.

"Pithecanthropus erectus" and the Evolution of the Human Race.

THE remarkable advance made by biology during the last twenty years in the study of the Tertiary mammalia, must strike even the most casual onlooker. It is not merely that an exact knowledge has been gained of a vast number of extinct forms, but that amongst these has been discovered a profusion of missing links, rendering possible the construction of ancestral trees, or diagrammatic illustrations of the successive stages through which existing animals may have been evolved from a common stock. Some of these "trees" may prove to be mere intellectual weeds, which to-day are, and to-morrow are cast into the oven; but others are of robuster growth, finding a firm support in geology, which has been able in many cases to certainly fix the order in which successive branches of the tree have budded forth. It is to be regretted that geology has not been able to do more than this; could it but succeed in the construction of a scale of past time, what fascinating prospects in the study of evolution would be opened out! The construction of such a scale is beset, however, by grave—possibly insurmountable—difficulties, as will readily appear from the following attempt.

For the present there appears little hope of connecting geological events with such astronomical processes as changes of eccentricity and the precession of the equinoxes, and the only method left for our adoption is that of estimating the maximum thickness of the successive systems of stratified rocks. This, however, is to a great extent vitiated at the outset by the heterogeneous character of these systems; some are wholly or in part marine, some fluviatile; some consist largely of organic, others of mechanical sediment; and it is impossible to reduce their various members to any common term.

As there is no alternative, we proceed to do the best we can with existing materials, and shall now endeavour to obtain some approximate notion of the relative duration of the last three periods in the earth's history, viz. the Pleistocene, Pliocene, and Miocene. The first and most recent of these was probably of longer duration than we are accustomed to suppose. Borings sunk in the deltas of existing rivers have seldom penetrated to the bottom, yet they have indicated a very considerable thickness of deposits; thus, in the case of the Po, a boring near the Casa di Dio, Venice, passed through 572 feet of sediment. Near New Orleans, the delta of the Mississippi was penetrated for 630 feet; while the fluviatile deposits of the Ganges were shown, by a boring near Lucknow, to exceed 1336 feet in thickness. In Alaska, however, as the observations of Russell prove, the Pleistocene attains a far greater thickness than this ("Second Expedition to Mount St. Elias in 1891." U.S. Geol. Survey, Thirteenth Report, part ii. p. 24, 1891–2).

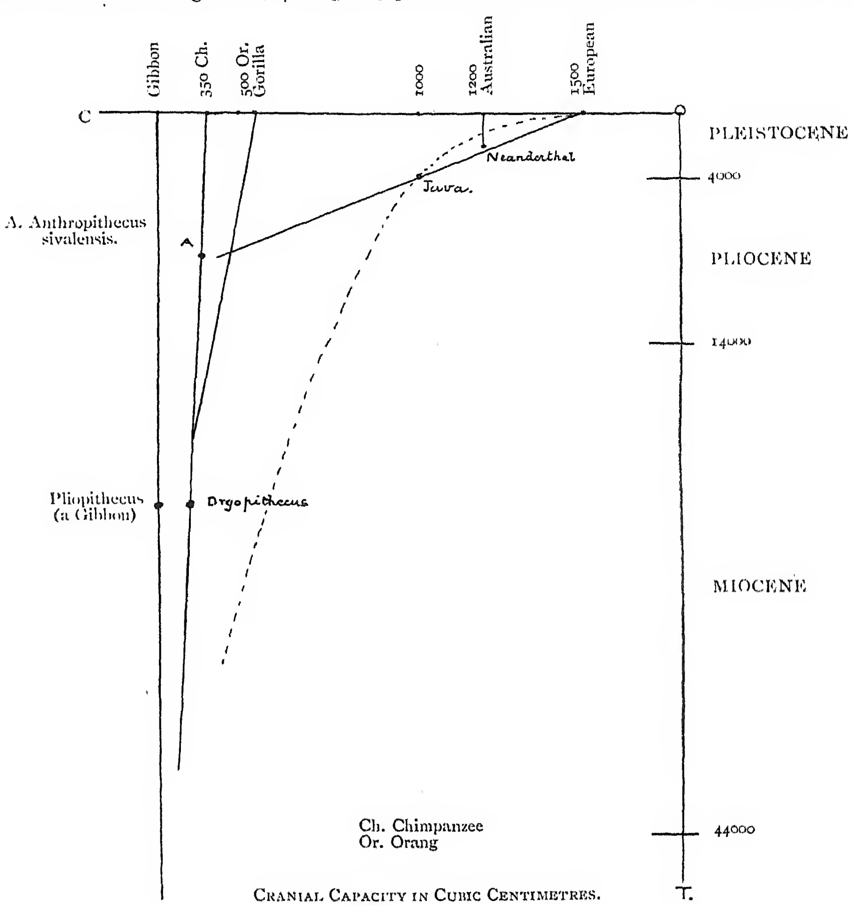
The following extracts from his report may prove generally interesting:—"The Chaix hills are geologically unique. They are formed of a monoclinal block of conformable strata eight or ten miles long, trending north-east and south-west, and tilted northward at an angle of 10° or 15°. . . . But what makes the hills especially interesting to the geologist is the fact that they are composed of stratified morainal material. . . . From many eye estimates it is evident that the minimum thickness of the deposit cannot be less than 4000 or 5000 feet. The rocks are essentially homogeneous from base to summit, and are composed of sandy clay containing large quantities of both angular and rounded boulders of all sizes up to six or eight feet in diameter. In the finer portions of the deposit . . . sea-shells are numerous. A small collection was made. . . . All [the species] are still living in the adjacent ocean. Besides the shells of molluscs, there are the shell-cases of annelids [*Serpula?*] attached to glaciated boulders, showing that the stones on which they grew must have remained exposed at the bottom of the sea for some time before being wholly buried."

It may be objected that these deposits differ so completely from those of the alluvial plain of the Ganges, in their nature and origin, that they might fairly be left out of account; but to this it may be replied that we have no reason for supposing that glacial denudation proceeds at a greater rate than fluviatile, indeed the reverse is probably nearer the truth, and though it is deposition and not denudation which is directly in question, yet the observation of Mr. Russell, that annelid tubes are found adhering to the embedded boulders of the deposit, certainly does not suggest an excessively rapid rate of accumulation. We shall take then 4000 feet as representing the maximum thickness of the Pleistocene system.

In a recent communication (NATURE, vol. li. p. 533) on the age of the earth, I gave 2000 feet as the maximum thickness of the Pliocene system, and this is the thickness which it attains in Europe (Sicily); but in India this is far surpassed, the Siwalik Hills, which are 14,000 or 15,000 feet in height, present for examination at least 10,000 feet of Pliocene deposits.

In Europe the Miocene does not exceed 6000 feet in thickness; but it may be regarded as quite certain that the duration of Miocene time was much greater than that of the Pliocene, and since in Europe the thickness of these two systems is as 3 : 1, we shall probably arrive at a just result if we take three times the thickness of the Pliocene of India to represent, on our scale, the duration of the Miocene period. We thus obtain for the proportional duration of our three periods the relation 0·4 : 1 : 3, which to the geologist has a veridical look.

In order to employ this scale to indicate the rate at which evolution in any particular case has proceeded, we must be able to give a numerical expression to the evolutional change also; and this can be accomplished, at least partially, in the case of the human race. For with it, the organ of organs is not so much the hand as the brain, and of this the volume at least can be ascertained, whenever we can possess ourselves of a human skull. In the following diagram the scale of time is plotted on the ordinate O T to the right, and the cranial capacity on the abscissa O C. The Neanderthal race is assigned to the middle of the Pleistocene, on the evidence of the Spy remains; the Java fossil is placed at the beginning of that period. Dr. Dubois is in possession of evidence which, when fully worked out, will fix its geological position with greater precision than we can attain at present; but so far as his published statements go, they point to that which we have assigned as the most probable horizon. The anthropoid apes are shown on the left of the diagram; the chimpanzee and gorilla are supposed to be the descendants of a chain of ancestors, which converge towards a common stem, on or near which Dryopithecus of the Middle Miocene is situated. This, which we may call the Dryopithecus stem, converges towards Hylobates. It will be observed that we have drawn all these lines of descent sloping towards the left, as they must almost certainly have done if there be any truth in evolution, and consequently the further back we go to find the origin of the human stem, the more brutal we make the primitive ancestor.



If now we draw a line through the point occupied by the average European skull, and that occupied by the Javan skull, we find that it passes very close to the Neanderthal, and this suggests that the evolution of the human race has proceeded at a very uniform rate throughout the whole of Pleistocene time, while the excessive slope of the curve suggests that this rate was a very rapid one. If further we produce this line to the left, it will be found to intersect the ancestral stems of the highest anthropoid apes in the middle of the Pliocene period, and it is to this period that *Anthropithecus sivalensis* of Lydekker, a chimpanzee having affinities with man and Hylobates, has been assigned. The exact horizon from which the palate, on which this species is founded, was obtained is not known; and in this connection one is constrained to express the great regret that all biologists must feel at the imperfect manner in which the Siwalik strata have been investigated. Beds said to be unfossiliferous are known to possess fossils, and of those specimens which have been obtained from the series specially distinguished as fossiliferous, the proper geological position is not known. The Siwalik beds, if carefully searched, might be expected, from what we already know, to yield results no less precious to science than those obtained by Marsh and Cope in the famous deposits of the Green River Basin. It might be well worth considering whether an expedition could not be despatched from Europe for the special study of the Siwalik sediments.

The suggestion offered by the curve running through the apes to man is that he is of comparatively recent origin, and derivative from the stem of the gorilla or chimpanzee before these species had acquired their existing specialised characters. The straightness of the curve has an aspect almost miraculous, not a discommendation to the minds of some; but it has this positive advantage, that by linking on the human to the pithecoid stem at a high level, it saves us from the invention of a superfluity of imaginary predecessors, and all that tends to parsimony in this direction is an evident gain. The evolution along a line of descent is not confined to the acquisition of new characters, but includes the loss of others; and thus I can see no reason why the human ancestry should not have proceeded from the comparatively highly organised ancestors of the gorilla or chimpanzee, rather than from the more primitive predecessors of Hylobates. To those who think otherwise the curve shown by dotted lines will appear the more plausible; if the Neanderthal skull be lifted a little upwards in the scale of time, a curve can be made to pass through it, the European and Javan skulls, and this when prolonged downwards will approximate to the stem either of Pliopithecus (a Miocene gibbon) or the more brutal Dryopithecus. This would be a curve indicating greatly accelerated development as it approaches modern times; a contingency which a preliminary examination of other groups shows to be by no means impossible. Other curves no doubt could be drawn according to fancy of the individual; the true curve may possibly reward some fortunate investigator of the Siwalik Hills.

Globular Lightning.

A GREAT deal has been written recently on the various forms of lightning, and the subject itself has so much scientific interest, that it may be worth while to place on record an observation of my own on globular lightning, made years ago, in which the main facts are different from any I have seen described.

On Tuesday, July 23, 1878, I was on board a large yacht at anchor in the harbour of Southampton, England. About two o'clock in the afternoon, when we were about to sail, a violent thunderstorm came up from the west, and as it passed over Southampton, several bolts descended, one of which, as I afterwards learned, struck a church. As the first drops of rain came down on the yacht, I was standing in the after-companion-way, looking forward, when my attention was attracted by a bright light apparently near the upper part of the foremast. When I first saw it distinctly, it was about half-mast high, and was falling slowly and directly toward the deck. This light was a ball of fire, a delicate rose-pink in colour, pear-shaped in form, with the large end below, and appeared to be four or five inches in diameter and six or eight inches in length.

When it struck the deck, about forty feet from where I was standing, there was a loud explosion, and it was some minutes before it could be ascertained what damage had resulted. The mate, who stood near the mainmast, about twenty-five feet from where I was, was knocked down, but soon recovered. The same bolt, or part of it, also passed in front of the foremast, down a windsail ventilator, into the galley, where it knocked a large tin pan from the hands of a cook, and upset things generally throughout the culinary department, but injured no one seriously. Of the crew, some were on deck, and others below, but none were really injured, although a few were badly demoralised. A strong ozone-like odour was observed immediately after the explosion, and this remained perceptible for some time.

The officer in charge of the yacht, Captain Matthews, who was forward at the time, and escaped without injury, stated that just after the stroke, he saw "streaks of lightning running around on deck like snakes." I was myself only dazed for a moment by the explosion, and saw distinctly that the deck forward was illuminated with a bright confused light. The owner of the yacht, George Peabody Russell, and his other guests, had gone below when the storm began, and suffered no injury, except possibly from fright, as they were still further away from the stroke.

As soon as the storm had passed, I made careful notes of the whole occurrence, with drawings and measurements, as I was much interested in the subject, and it was the first instance of the kind I had seen at close quarters. An inspection showed that the vessel itself had sustained no material damage, and there were not even permanent marks left on the deck where the ball of fire exploded. A number of other yachts were at anchor quite near our vessel at the time, among them the white *Sunbeam*, just home from her well-known voyage, but we saw no indications that any of these had been struck. I had no time to inquire, as immediately after the storm we sailed on a cruise to the eastward.

O. C. MARSH.

Yale University, New Haven, Connecticut, December 4.

Large Human Femora in the Church of S. Eustachius, Tavistock.

TAVISTOCK ABBEY was founded A.D. 961 by Orgar, Earl of Devonshire, and endowed and completed by his son Ordulf A.D. 981. Some bones, said to have been found in an ancient stone coffin in the Abbey ruins, are locally believed to have once formed part of the skeleton of the said Ordulf, a reputed giant. According to William of Malmesbury, this Ordulf could stride across a stream ten feet wide, and he is said, by the same authority, to have torn off the bars from the town gate of Exeter with his hands, and to have wrenched away the hinges with his feet.

The relics, which are preserved under glass in Tavistock parish church, consist of three thigh bones which originally belonged to three different individuals.

Whilst at Tavistock recently I had an opportunity of measuring these bones: the extreme length of one is 1 ft. $9\frac{1}{8}$ in., the second 1 ft. $8\frac{5}{8}$ in., and the third 1 ft. $5\frac{1}{4}$ in. The heights of the original owners were therefore 6 ft. $8\frac{1}{2}$ in., 6 ft. $5\frac{1}{2}$ in., and 5 ft. $5\frac{1}{4}$ in. The two larger bones appear to have belonged to strong well-developed men, the other bone is more delicate.

Dunstable. WORTHINGTON G. SMITH.

A Lecture Experiment in Surface Tension.

WISHING to demonstrate to a fairly large audience the well-known disastrous results of attempting to remove grease stains by placing ether or benzol *on* them, instead of *round* them, and then spirally approaching their centres, I hit on the following plan, which gives not only unmistakable but beautiful results.

A circle of paraffin or olive oil is painted on the centre of a filter-paper, which is then dusted over with bone-black. A light blast of air on the paper removes the bone-black from all portions of the paper except the oiled portion, which looms up jet-black on a pale grey ground. The filter-paper is then folded in four wings, so that its edge forms a curved cross, and it is secured in this position by a penholder which has two longitudinal slits cut at right-angles. (This method of folding and securing will be familiar to all who can recall their school-days to the minutiæ of "penholder darts.")

The tip of the oiled apex of the filter-paper is dipped for a moment or two in ether. The paper is then unfolded, dried, and subjected to a second treatment with bone-black, when it will be found that the ether has chased the oil from the apex, and spread it towards the circumference of the paper in a symmetrical pattern.

It is scarcely necessary to add that there is no virtue in the special method of folding described above, and that a great diversity of beautiful patterns may be obtained by folding the filter-paper, and distributing the oil in other ways.

The Leys School, Cambridge. DOUGLAS CARNEGIE.

An Examination Question in Physics.

IN the subject of Experimental Physics, B.Sc. Examination for Honours of the University of London (December 5), the fifth question of the second paper stands as follows :—

"A plate of uniaxal crystal, cut with the faces *parallel* to the axis, is placed between a polariser and an analyser. How would you arrange a source of light and lenses to show a system of *rings* on a screen?

"Explain how the rings are formed when the polariser and analyser are crossed and the *axis is in the plane* of polarisation of the incident light." (The italics are my own.)

As the B.Sc. Honours is the highest examination of the University, the questions set therein are naturally regarded by students as important tests of knowledge; and I think it would, therefore, be of considerable scientific interest if the examiners would kindly state their intention in setting this question, and the nature of the answer they expected to receive.

Queen's College, Harley Street, W. E. F. HERROUN.

"Linotænia maritima" (Leach).

WILL you kindly allow me to put on record a new locality for this marine centipede?—Bexhill, just above high-water mark. The single specimen taken was kindly identified for me by Mr. R. I. Pocock, of the British Museum (Natural History).

HENRY SCHERREN.

THE TRANSFORMATIONS OF INSECTS.

SO much special work has been done during the last thirty years upon the transformations of insects, that I lately resolved to spend some time in reviewing the most important facts which have been ascertained respecting the structural changes which take place before or during pupation. I had not gone far before I found it necessary to clear up my own thoughts as to the nature of insect metamorphosis, and the way in which it had come about. Some preliminary considerations upon these points, inferred from facts which have long been known, I now propose to discuss, leaving the more special facts to some future occasion.

Three naturalists, Fritz Müller (1864),[1] Friedrich Brauer (1869),[2] and Sir John Lubbock (1874),[3] have in

1 "Facts for Darwin" (Für Darwin).
2 *Verh. Zool. bot. Ges. Wien* (1869). Of less importance is Part 2 (1878).
3 "Origin and Metamorphoses of Insects." (Appeared originally in NATURE, 1873).

our own time written upon the origin of insect transformations. It was, as they themselves tell us, Darwin's "Origin of Species" which incited each of them to look at the old facts in the light of a new theory. Fritz Müller, being at the moment specially occupied, not with insects, but with crustaceans, threw out casually, as it were, a number of general results of the greatest interest and value, which he did not attempt to support nearly so fully as his own knowledge of insects would have enabled him to do. Brauer, a little later, travelled over the subject in a somewhat more leisurely way. The most important principles had already been indicated by Müller, but he was able to contribute many facts of special interest, and to point out a definite and rather widely distributed larval stage, of which much has since been said in discussions on the phylogeny of insects. I need not remind English naturalists that, even before 1874, Sir John Lubbock had won fame by his researches into the life-history and habits of insects. He had also written specially upon insect transformations before he collected his matured thoughts into a book. His "Origin and Metamorphoses of Insects" is now very widely known. It is by far the most readable exposition which we possess, and will long hold its place as an interesting account in simple language of that part of the subject which involves no special knowledge of insect anatomy. Some day it should be supplemented by an account of the mechanism of pupation, showing in detail how various larvæ are converted into winged insects. It is on this side that insect transformations have been most successfully attacked during the last thirty years.

It is natural that after an interval of many years we should find what seem to be deficiencies in the work of those who have gone before us. The most notable deficiency which I find in Lubbock's book is that he does not remark the great distinction between insect metamorphoses and those of most other animals.[1] They occur, as I think, in a different part of the life-history, and arise out of conditions which are different, or even diametrically opposite. There are other points, too, which seem to me to be passed over too briefly by Lubbock and all previous writers. In particular, certain aphorisms of Fritz Müller seem to me to deserve a fuller explanation than they have yet received.

Such inevitable gaps in the expositions of our predecessors render it possible to supplement even works which have attained the rank of classics. Each generation for a long time to come will be able to add its quota of facts and reflections without exhausting this immense and difficult subject of inquiry. It is satisfactory to note that Lubbock's account has been very little disturbed as to matters of fact by later investigations, so that his readers, though they have plenty still to learn, have very little to unlearn.

Let me first attempt to justify my contention that the transformations of insects are fundamentally unlike the transformations of polyps, echinoderms, mollusks and crustaceans. In the marine groups the minute animal, just escaped from the egg, passes rapidly through its changes, often before the yolk is absorbed. It may complete them before it begins to feed, always long before it has attained its full size. The insect, on the contrary, undergoes its most striking change of form after it has attained its full size. Moreover, the planula of the polyp, the bipinnaria or pluteus of the echinoderm, the Nauplius or Zoæa of the crustacean, are unknown except as transitory forms. But the less specialised insect-larvæ make a very close approach to certain lower, wingless insects in their adult state. The insect-larva, before it gives place to the pupa, has not only attained its full size, and acquired a form answerable to that of some perfectly adult insects, but it already contains in many cases completely developed reproductive products; indeed, a very few insects are known to be capable of reproduction as larvæ. It seems to me preposterous to say, as Harvey did in the 17th century, that the insect-larva is a kind of walking egg, or with Quatrefages, that it is an embryo which leads an independent life. It would be far more truthfully described as an animal which has attained the normal structure of adult Arthropods, though it has still to undergo a peculiar adult transformation. Where the insect larva falls short of that adult structure, it is because abundance of food, or some other external circumstance, has induced degeneration, but we shall best understand insect-larvæ in general by comparing them to sexually mature myriopods, protracheates, scorpions and Thysanura.

Adult transformation is rare among free-living animals, though parasites furnish many examples. The Ctenophora, instead of settling down early, maintain a pelagic life, and became specially modified thereto in a late stage of development. The secondary sexual characters assumed by some birds and mammals at the time of sexual maturity, such as the train of the peacock, or the antlers of the stag, are analogous facts. But the closest parallel to the transformation of insects is to be found in the Amphibia. Frogs and toads, having already as tadpoles attained the full development of the more primitive Amphibia, change to lung-breathing, tailless, land-traversing animals. The motive is the same as that which led to the acquisition of wings by insects. It is by virtue of their adult transformation, that both the amphibian and the insect are enabled to wander from the place of their birth, to seek out mates belonging to other families, and to lay their eggs in new sites.

In those Amphibia which undergo transformation, the stage added to the life-history of the more primitive forms is not the tadpole, but the frog or toad. In those insects which undergo transformation, complete or incomplete, the winged state is the new addition. If a pupa appears in the life-history, it results indirectly from the acquisition of wings by the adult. Hence it seems to me that in Amphibia and insects the peculiar change, which renders possible all the rest, belongs to the adult condition, *i.e.* these animals undergo an *adult* metamorphosis.

Transformation in the inhabitants of the shallow seas is closely related to the crowded state and severe competition of the area. The connection is two-fold. Unusual risks imply numerous eggs, numerous eggs must be small, and small eggs, with little or no yolk, hatch early, producing very immature animals, unlike their parents. Again the risks of the shore favour heavy-armoured species, and it is well-known that a great proportion of the invertebrate fauna of the sea-shore is defended in this way. But heavy armour diminishes activity, and in particular often renders swimming impossible. The dispersal of the species is therefore left to the young fry, which are often specially organised for locomotion at the surface of the sea. Marine animals which are not armoured, such as the Cephalopoda, may undergo no transformation at all.

Certain general propositions concerning larval transformation are disturbed if the adult transformation of insects and Amphibia is included. Indeed, I was first led to notice the distinction between adult and larval transformation by observing that insects and Amphibia do not conform to the general rule, that while the inhabitants of the shallow seas go through transformations in early life, fluviatile and terrestrial animals do not.

Every animal and every plant has these two functions

[1] I am not aware that any one else has made more than a passing allusion to this distinction, but I may easily have overlooked some important reference in the vast literature on insect transformations. Macleay has remarked that in insects the change of form takes place during their last two or three stages, whereas "the metamorphosis of all other Annulosa only occurs during the first or second moult after leaving the egg." (*Illustr. Zool. South Africa*, p. 53). I do not find this distinction recognised as part of ordinary biological knowledge in our best treatises on development, such as Balfour, or, Korschelt and Heider.

(among others) to fulfil. It must feed and grow; it must also separate from its fellows, and find out an unoccupied site. The two functions may be discharged together. Birds, for instance, feed all round the year, and change their abode whenever they suffer from overcrowding or scarcity of food. In other cases, either function may for special reasons be limited to a particular time of life. The crustacean cannot migrate effectively when adult, because of the heavy armour which it carries. The insect cannot migrate effectively when young, because of the difficulty of travel by land. It is easy for a minute animal to travel by sea. The high specific gravity of the water renders the body buoyant, and currents, even where special locomotive organs are absent, will do the work of transport. Power to rise and sink in the water is convenient, but even this is not strictly indispensable. On land the conditions are very different. The weight of the body has to be supported in a comparatively rare medium, and much greater exertion is called for Running, leaping, and flying are difficult exercises, much better performed by the adult than by the larva, if these should happen to differ materially.

It is often of advantage that there should be division of labour between the several stages of the life-history, and the functions of migration and growth may be allotted to special times of life instead of being carried on throughout. Migration is naturally associated with lightness and activity; feeding and rapid growth are favoured by a sedentary habit. If such division of labour should take place, as it commonly does in crustaceans and insects, the crustacean will find it convenient to perform its migration early, when it has little armour to carry, and when its surface is large in proportion to its weight. The Zoœa will do little more by its own exertions than maintain the right attitude and the right distance from the surface of the sea, leaving the currents to effect the actual transport from place to place. Migration over, it will settle to the bottom, acquire heavy armour as a defence from its many enemies, and begin to feed in earnest, becoming in the end a slow and heavy inhabitant of the sea-bottom. With the insect the procedure will be reversed. Being unable to travel far while small and weak, it will feed first, and having attained its full size, will then, if at all, acquire special means of locomotion. Wings are more efficient as a means of transport than any other organs of locomotion of which a terrestrial animal can avail itself; but flight is so difficult an exercise that wings, if acquired at all, will be acquired late.

Marine animals commonly produce far more eggs than insects.[1] The risks of the shallow seas are so great that a small proportion only of the young animals comes to maturity. Hence the enormous fertility of common marine animals, except such as are able to nourish or defend their young. Where a vast multitude of eggs hatch out together, dispersal in search of food becomes an immediate necessity.

The more sluggish and sedentary the adult, the greater the activity we may expect to find in the larvæ. It is they which have to travel and to find out suitable quarters. But they often make up by their numbers for any deficiency in enterprise or intelligence. Vast numbers of Zoœas are swept into mid-ocean or into tidal rivers, or are devoured. It is only a chance remnant that survives.

Just as the sluggishness of the adult crustacean or echinoderm may promote activity in the young, so the activity of the adult insect may discourage activity in the young. The power of flight possessed by most adult insects favours a sedentary life in the larva, which is spared all effort in connection with the dispersal of the species, and can give its undivided attention to feeding. Accordingly the larva often degenerates more or less, especially when its food is abundant and obtained without labour or risk. The sagacity and industry of the bee in storing its cells with honey may be said to have cost the larva its legs. So, too, the active and highly-gifted blow-fly, ichneumon, and gall-fly secure abundant food for the new generations, which emerge as footless grubs. In the Coleoptera we find that the larvæ, which feed on dead vegetable matter beneath the surface of the ground, are heavy-bodied and short-legged, sometimes so overloaded by the weight of the abdomen that they rest lying on one side. The larvæ of weevils, which are vegetable-feeders and often buried in the plant which they devour, are commonly without legs altogether. Even the head of the larva may be reduced almost to nothing by the labours of the adult insect. The blowfly finds out a practically inexhaustible supply of carrion in which to lay its eggs, and the larval head is so reduced that it consists mainly of a pair of large hooks, with muscles to work them, and a chitinous frame to form a fulcrum for the muscles.

The degeneration of the larva can only proceed far when the adult undertakes the dispersal of the species. That is why, it seems to me, the larvæ of marine animals, though often very unlike their parents, are not really to be called degenerate. They cannot be supposed to have arisen from ordinary forms, typical of the class, by mere disuse and reduction of the organs of active life. On the contrary, they are often immature forms specialised for locomotion.

Even when the adult undertakes the dispersal of the species, the larva does not necessarily become degenerate. The winged locust is the chief agent in dispersal, but the larvæ are active, seek their own food, and exhibit no marks of degeneration. It is only when their choice and responsibility are taken away, when they are encouraged to feed almost without intermission, or to bury themselves out of sight, that they degenerate.

Parental care and all labours undertaken by the parent for the sake of the offspring tend to promote helplessness in the young. The helplessness of the higher Vertebrates at birth, as well as their prolonged fœtal development, are due to the fact that their parents are able to find them food and protection. Here there is no degeneration in the young; though helpless, they are of the same zoological grade as their parents. The locomotive organs and the senses of a baby or a nestling bird are as complex as those of the adult, and are merely feeble for want of skill and exercise. In the larval insect there may be real degeneration, fewer limbs, fewer joints in the limbs, deficiency of sense-organs, relative preponderance of the organs of nutrition. If the transformation of insects had never been traced, the structure of the two stages would have inevitably led zoologists to place the caterpillar in a lower class or order than the butterfly.

There has been much speculation as to the form of primitive insects. Fritz Müller supposes that the wingless Orthoptera come near to the original stock, while others have derived all insects from the wingless and non-metamorphic Thysanura. By taking what is common to the least modified Orthoptera and the Thysanura, and rejecting all features peculiar to either, we shall certainly get a highly generalised insect, such as might possibly be a common ancestor for the whole group. Brauer pointed out that such primitive insects still survive in Campodea and Japyx, which have mouth-parts (as Lubbock considers) "intermediate between the mandibulate and haustellate types," one pair of many-jointed antennæ, three pairs of long legs, and an abdomen whose first seven segments bear pairs of rudimentary appendages, while the tenth and last segment bears in Campodea a pair of many-jointed appendages, in Japyx

[1] No statistics have been collected to my knowledge on an extensive scale. Very many insects lay their eggs singly. In particular cases (social insects, Meloidæ, &c.), where special reasons obtain, they may be laid in great numbers, but my general impression is that the eggs of Echinoderms or marine Crustaceans would be far more numerous as a rule.

a forceps. Campodea and Japyx have no eyes, but this is not considered typical; simple eyes are usual in insects of the same grade. They undergo no metamorphosis.

Brauer finds forms closely resembling Campodea among the larvæ of Orthoptera, Perlidæ, Odonata, Ephemeridæ, Coleoptera and Neuroptera. In Strepsiptera and Coccidæ he considers that they are present in a more modified form. No Campodeiform larvæ occur among Lepidoptera, Hymenoptera, or Diptera.

Brauer looks upon the caterpillar of Lepidoptera, Sawflies and Panorpa as a degenerate Campodea, while he considers the apodous maggot of many Coleoptera, some Neuroptera, Bees and Muscidæ as a still more degenerate larva, derived from, and not historically antecedent to, the Campodea. Grassi and others have brought forward facts to show that the maggot-like Bee-larva has previously passed through a kind of Campodea-stage.

Lubbock regards the caterpillar too as essentially a Campodea. But this extension seems to me to take all definiteness out of the Campodea-form. If every larva with biting mouth-parts and six legs is to be called a Campodea, we still want a name for the larva which has long legs, long antennæ and at least one pair of abdominal appendages.

Brauer's Campodea seems to invite comparison with Scolopendrella and Peripatus; just as the more generalised Campodea of Lubbock invites comparison with the hexapod larva of Diplopoda and Atax. I do not venture to pursue these comparisons, which involve difficulties not apparent at first sight, and will only remark that the former comparison seems to throw most light upon the phylogeny. The leg-bearing segments of the Diplopoda are apparently not the same as those of insects, and the embryology of insects points to a polypod, rather than to a hexapod, as the common ancestor of the Tracheates.

If it seems rash, with our present knowledge, to trace the phylogeny of Peripatus, the Myriopods and the insects, what shall we say of Lubbock's far bolder attempt to derive his Campodeiform larva from a Rotifer-like ancestor? It is suggested, though not positively asserted, that certain apodous dipterous larvæ exemplify this earlier stage. I must declare myself altogether sceptical as to a Lindia-stage antecedent to the Campodea. The only apodous insect-larvæ known to me are born of highly specialised insects, and have apparently become degenerate in consequence of the completeness of the provision made for them by the intelligence or special instincts of the parent. They are, as Brauer humorously says, like the sluggards in Hans Sachs' Lubberland, who required roast pigeons to fly into their mouths. I see in them no mark of a primitive insect.

Brauer in 1869 was ready to derive the maggot from the caterpillar, and the caterpillar from the Campodea (p. 310). He points out, very truly, that the reduction of the larval head of the Diptera may be gradually traced from forms in which it is perfectly developed. It is a pity that he did not bear his own explanation in mind when at a later date he attempted to arrange the Diptera Nemocera by characters largely drawn from the degree of development of the larval head. The unsatisfactory nature of the result has been pointed out by Baron Osten Sacken (*Berl. Ent. Zeits.*, Bd. xxxvii. p. 417, 1892).

That Brauer's arrangement of the Nemocera does not, in the opinion of experts, associate allied forms, shows that he has been unfortunate in his use of larval characters. Could that result have been anticipated? Is there any general objection to the employment of larval characters in the definition of large groups of insects? I think that there is. In his paper of 1869 Brauer, following Fritz Müller, remarks that the development of various insects has been either abbreviated or falsified. He thinks that the Hemiptera have lost a transformation which they once possessed. He thinks that Dipterous larvæ and others have been acted upon by conditions of life which have not affected the imago. Yet he has employed characters which he knew to be highly adaptive and also finely gradated, for the definition of his tribes and families. Brauer is both a systematist and a philosopher, but his system forgets his philosophy.

Primitive insects, we may suppose, attained the Campodea form in the egg, after which they merely increased in size without important modification of structure. The next step opened the way to extraordinary developments, which were not, however, immediate or necessary consequences. Certain insects acquired wings as adults, while others remained wingless and pursued the old life. The acquisition of wings did not as a matter of course greatly affect the habits of the species. Some, like the grasshoppers, crickets, and cockroaches of to-day, continued to run about on their long legs in all stages, and divided their food with the same kind of jaws as their wingless progenitors. But when full advantage was taken of the new means of locomotion, the life-history was profoundly affected, the two extremes, early and late, being acted upon in opposite ways. The imago grew more active and quicker to discover the best sites for egg-laying, gradually undertaking the whole function of dispersal of the species. The larva, thus relieved from choice and travel, became slow and clumsy, escaping its enemies by protective resemblance or burrowing. It came to be more and more exclusively occupied with feeding, while the adult, except where the business of egg-laying was unusually protracted, fed less and less, sometimes not at all.

The quiescent pupal stage seems to me to have arisen from the contrast between the degenerate, slow, voracious larva and the active, highly organised and sensitive imago. Sagacity and activity gradually declined in the larva, and became exalted in the imago, until the extremes of the life-history became so unlike that they could only be reconciled by profound changes, incompatible with locomotion and feeding.

I quite agree with Lubbock's remark, "that the apparent abruptness of the changes which insects undergo, arises in great measure from the hardness of their skin, which admits of no gradual alteration of form, and which is itself necessary in order to afford sufficient support to the muscles." The hardness of the skin in insects and other Arthropods involves periodical moults in order that the body may increase in size. Pupation is an exaggeration of one of these moults, the subsequent escape of the imago is an exaggeration of another. These two moults are the last but one, and the last of all, and the pupal stage, where there is one, intervenes between them.[1] An ordinary moult gives opportunity for effecting slight changes in the chitinous cuticle. The new skin is not necessarily moulded precisely upon the old one. If increase of size is required, the new skin can be made a little larger, and accommodated within the old one by wrinkling or folding. It is in this way that the wings of an Ephemera, a dragon-fly, or a male cockroach gradually attain their full size. If projections of unusual length are to be formed beneath the old skin, they can easily be telescoped into the body; a process which attains a high degree of complexity in some insects.

Many insect transformations, too familiar to be detailed here, illustrate the great facilities afforded by the change of skin for replacement of organs lost by degeneration, or for development of new ones, more elaborate than any possessed by primitive insects. But for these facilities I imagine that larval degeneration would never have gone so far as it has done in insects; the price to be paid would have been too heavy.

[1] It has come to pass, by some process which I cannot trace, that in Ephemeridæ, where there is no pupal stage, the fly quits the water at the last moult but one, and immediately afterwards casts another very thin skin.

How insects first acquired wings, and from what structure they were derived, is still a profound mystery. A favourite conjecture is that they arose by the modification of tracheal gills. In favour of that supposition is the fact that in some dipterous larvæ (Chironomus, Simulium, Culex, Muscidæ), three pairs of rudiments (imaginal folds) form on the dorsal surface of the thoracic segments, and as many on the ventral surface. The ventral rudiments ultimately become the legs of the fly. Of the dorsal rudiments the second becomes a wing, the third a rudimentary wing, and the first the respiratory organ of the pupa, which may take the form of a trumpet or a bunch of branching tubes. In the larvæ of the Muscidæ this anterior dorsal appendage is said by Weismann to form much later than the rest, only during the last larval stage, and to be greatly inferior in size. In Chironomus and Simulium it forms at the same time, and is quite similar to them. Where an anterior spiracle exists, as in the Muscidæ, the anterior dorsal appendage forms close behind it, and ultimately replaces it. Now, if it could be clearly shown that all three dorsal appendages form one series, and that one or two are converted into wings, while the foremost becomes a breathing-organ, we should at least know that a wing and a breathing-organ may have a common origin. So much seems probable, but we must still wait for conclusive facts before we can explain how insects first got their wings.

In many Orthoptera, and other hemimetabolic insects, effective wings are developed without any resting-stage. I think that we may safely infer that historically wings were acquired before complete metamorphosis set in, and before insect-larvæ underwent degeneration.

Though the fact must, of course, be well known, I do not remember that any zoologist has expressly mentioned that the resting-stage of insects is unique among animals. The nearest phenomenon of the same kind is the encystment of certain Protozoa and parasites; but cessation of all the functions of active life, when these have once been assumed, for the purpose of effecting a definite advance in organisation, is a thing peculiar to insects. Hence we cannot check our interpretations by examples taken from outside the class. But all insects do not pupate, and we may learn something by studying the hemimetabolic insects in which there is no quiescent pupa.

Nearly all these insects (some few Orthoptera and some Rhynchota are exceptions) ultimately acquire wings, the rudiments of which may be externally visible long before the imago stage is reached. In hemimetabolic insects it is unusual to find any marked change in the food, the mouth-parts, the general form of the body, the texture of the skin, the length of the legs, the muscles, or the nervous system. It is often difficult to distinguish a full-sized larva from the imago without close examination. In Ephemeridæ, Perlidæ, and Odonata the larva is aquatic and the imago aërial, so that notable changes appear in the mode of respiration, but still the transition is effected without a resting-stage.

We have seen that wings may be acquired by insects which pass through no pupa-stage. There is, however, hardly a case (the parasitic flea is one) of an insect which pupates without acquiring at least the rudiments of wings in one or other sex. The main purpose of pupation would in general be defeated if the adult were wingless.

Change in the form of the mouth-parts, if so considerable as to involve a new method of feeding, *e.g.* the substitution of sucking for biting, cannot be effected without a quiescent pupa-stage. It seems inevitably to involve a rather prolonged interval during which the old mouth-parts are not in working order, while the new ones are not yet complete. But though considerable changes in the mouth-parts imply a quiescent pupa, they are not the sole reason for pupation. The larva and imago of many Hymenoptera and Coleoptera have similar mouth-parts, yet they all pupate. Neither acquisition of wings nor great changes in the mouth-parts can be the sole reason for pupation, for pupation is not indispensable to acquisition of wings, and it is not always followed by material changes in the mouth-parts.

Lubbock quotes from his earlier memoir on Chloeon (*Linn. Trans.*, vol. xxv. p. 486, 1865), the remark "that the occurrence of metamorphoses arises from the immaturity of the condition in which some animals leave the egg." Insects are specially referred to, for in the memoir quoted we are told that the necessity for change depends on the fact that most insects leave the egg in a very early condition, and that this again is probably owing to the fact that the amount of nourishment in the egg is insufficient to carry the insect to maturity. Brauer adds that the eggs of insects with complete metamorphosis are regularly smaller in proportion to the parent than those with incomplete metamorphosis or none.

I believe that Lubbock's explanation is true of many marine invertebrates, but not of insects. The vast number of eggs laid by a crab or a sea-urchin is very likely one cause of the smallness of the eggs and of the unlikeness of the larva to the parent. The transformation which assimilates the larva to the parent is in such cases effected as soon as possible after the migatory larva has settled down and begun to feed. But in the insect there is, as a rule, no important advance in structure during almost the whole of the larval period. If deficiency of nourishment had occasioned a temporary arrest of development, abundance of nourishment would surely have made up the loss sooner. The time of pupation seems to me too distant from the time of hatching, especially as the whole period of active feeding and rapid growth intervenes, to be entirely due to the conditions of nourishment of the larva in the egg. Special facts, of which many could be cited, tell against Lubbock's explanation. The Staphylinidæ commonly lay relatively large eggs, and yet undergo complete metamorphosis. Some insects actually retrograde before hatching out, and lose legs which they had already acquired, a pretty clear proof that want of nourishment was not the cause of what is called their immaturity at birth. The state of the insect at hatching seems to me to depend far more upon the conditions of larval life than upon the supposed privation of nourishment during embryonic development.

It is plain that insects have gained very much by complete metamorphosis. The extraordinary numbers and range of the holometabolic insects settle that fact decisively. If further proof were required, we might point out that the resting-stage or quiescent pupa seems never to have been lost in any insect which once possessed it. It is hard to prove a negative, but I cannot call to mind a single clear instance. So powerfully has adaptation acted upon insects that almost every organ and almost every stage is known to disappear at times. Wings, legs, eyes, mouth-organs, head, are known to be deficient in the larva, and a very few adult insects have no functional wings, legs, eyes, or mouth-organs. The single order Diptera furnishes us with examples of suppression during the larval stage of all these organs. The egg, the larva, the winged imago may disappear as independent stages in the pupiparous Diptera. But the quiescent pupa remains in every case where it can be shown to have once existed. At most the pupa (in holometabolic orders) becomes in some degree capable of locomotion; it never feeds.

We cannot reckon among the advantages secured by complete metamorphosis the acquisition of wings, for many insects which acquire wings have passed through no resting-stage. Among these hemimetabolic insects are the dragonflies, which take their prey on the wing, but in general the hemimetabolic insects gain nothing by flight, except facilities for dispersal and egg-laying.

The female ant, and apparently the Ornithobia, lay aside their wings as soon as the eggs are fertilised. In adult hemimetabolic insects the mouth-parts are either like those of the larva, or not functional at all; the form of the body, the texture of the cuticle, the organs of sense, and the legs are in general those of the larva, so that we might consider the imago as merely a winged and sexually mature larva.

But the imago of the holometabolic insect is always more than a winged and sexually mature larva. It differs in the form of the body, in the internal anatomy, in the organs of special sense, and usually in the structure of the mouth-parts. Perhaps the smallest advance upon the larva is seen in the imago of the Adephagous Coleoptera, but even here, though the mouth-parts are generally similar and the wings often rudimentary, the difference between the adult and the larva is much greater than in a locust, cricket, or cockroach. Some anatomical comparisons which I have made between the larva and imago of the Carabidæ, point to great changes in the muscular system as sufficient to explain the retention of the resting-stage even in the absence of other motives. The changes in the muscular system are rendered necessary by extensive changes in the shape of almost every segment and every appendage. But the reason of these changes of shape is sometimes hard to discover.

The greatest advantage won by holometabolic insects is access to the pollen and honey of flowers. Both flowers and insects benefit by mutual help, and have become specially modified to make the most of it. Perhaps no ametabolic insect regularly visits flowers. Some small Hemiptera, which are hemimetabolic, do so, but I believe that their visits have not called forth any special adaptation on either side. The Coleoptera, though holometabolic, have biting jaws, and this may be the reason why so few of them regularly haunt flowers. Hermann Müller tells us that some tropical beetles have the maxillæ specially modified for honey-sucking.

Three large orders of highly-organised insects contain a greater or less number of honey-sucking species. These are the Diptera, the Hymenoptera, and the Lepidoptera. The honey-sucking Diptera are comparatively few, but they are of importance to flowers, many of which depend upon their visits for the fertilisation of their ovules. The honey-sucking Hymenoptera are the bees. Of all insects these make the greatest use of honey and pollen, feeding upon it throughout life; they exhibit a more elaborate collecting apparatus, and have acted with more effect upon the organisation of flowers than any other insects. In Lepidoptera honey-sucking becomes more frequent than in any other order. Every moth and butterfly that feeds at all sucks honey, to pass over such unimportant exceptions as the fruit-eating moths with perforating proboscis.

It is a striking proof of the importance of insects in nature that they should have been able to call into existence a profusion of beautiful flowers. All the flowers of the garden and conservatory, all the wild flowers which delight us by their perfume, colour, or form, are in a sense the work of insects. What they found ready to hand was a multitude of green or sober-tinted flowers of small size, without honey or scent; the visits of insects have done all the rest. Flowers have done almost as much for insects as insects have done for flowers. Flowers are to innumerable tribes of insects all that domestic animals and cultivated plants are to mankind. Honey, which may be considered a joint product of the flower and the insect, owes its great importance to three properties. It is fluid, it is highly nutritious, and it can be stored without undergoing putrefaction. Its fluidity and concentration render it particularly suitable as a food for those winged insects which lay their eggs singly or a few together on scattered plants of one kind, and which must, therefore, spend much time in egg-laying, as well as to those which spend much time in excavation or building. Upon the fact that honey can be stored for many months depends the whole domestic economy of many species of bees and ants. The chemical possibility of the conversion of honey into wax was a discovery made by bees to the great advantage of their architecture. Not only have special instincts been founded upon the properties of honey, but its pursuit has led to increased swiftness on the wing, keener perception of colour and distance, as well as to obvious modifications of mouth-parts and stomach.

Like other facilities which encourage activity and intelligence in the adult, honey-sucking tends to arrest the development of the larva. The parent undertakes all responsibility and labour, and leaves the young with nothing to do but to feed and grow.

Honey-sucking is associated, but not rigidly or indispensably, with the highest faculties ever attained by insects. It marks, perhaps, the highest phase in their evolution. No insect can get so high without passing through a quiescent pupal stage, for without metamorphosis it cannot acquire organs of sufficient delicacy. Those which attain to honey-sucking have within their reach all the accomplishments and all the civilisation of which any insect is capable.

To any one who considers the great importance of honey in the life of the higher insects, it is a surprise that ants should have climbed so high without honey-sucking. They have biting jaws, and the workers have no wings. Hence they are useless for the fertilisation of flowers, and many flowers have developed elaborate obstacles for the express purpose of excluding ants. Ants, however, do supply themselves with honey in spite of all obstacles. They will get it from Aphides if no better way can be found. Some ants have learned to store honey in subterranean receptacles, the most singular of which are the enormously dilated crops of certain individuals of the community, which sacrifice themselves for the good of the rest, and are converted into enormous, globular honey-pots. The Myrmecocystus of Mexico, and the Camponotus of Australia, furnish us with examples.[1]

It would seem as if ants had sacrificed their wings for the sake of carrying on their subterranean life with greater ease. They have paid a heavy price for this advantage, for loss of wings in the end involved exclusion from flowers. The bees have managed to keep their wings, and yet to build elaborate structures for the family.

Beginning with the Campodea form, insects have ascended through several degrees of specialisation, acquiring first wings, then complete metamorphosis, and lastly attaining to honey-sucking. They have also descended through equally marked stages, losing length of limb first, then losing their limbs altogether, and in extreme cases losing their heads and jaws almost completely. The highest perfection of the insect-type is always found in the adult, the lowest degeneration in the larva. To the intervention of the resting-stage is due a singular relation between the two processes of evolution and degeneration, which is, as far as I know, peculiar to insects. In insects, as a general rule, the higher the organisation of the adult, the lower the degeneration of the larva. The complete metamorphosis of the Coleoptera, Lepidoptera, Hymenoptera and Diptera has rendered it possible for their larvæ to degenerate, and yet recover in a later stage all that has been lost. The grubs of the weevil and the bee would not have lost their legs if the parent had been unable to provide them with a store of food sufficient for the whole larval period, which could be devoured without leaving the place of hatching. The maggot would not have lost head and

[1] Lubbock, "Ants, Bees, and Wasps," p. 19.

jaws if the fly had been unable to lay its eggs in an abundant supply of highly nutritive food.

The illustrative table will render it easier to realise that in insects as a general rule, special development upwards involves special development downwards in an earlier stage, and also that only a very moderate difference between the extreme forms of the larva and the adult can arise without a resting-stage. Abundance of food, and a life without exertion, often render the larval skin soft and extensible. Since in insects the chitinous

cuticle furnishes a chief part of all the organs of locomotion, of prehension, and of special sense, a soft, extensible skin involves complete degeneration. This may last throughout the whole larval period, during which the external conditions are usually the same. Then comes the sudden change to a stage in which a maximum of activity and intelligence is called for.

It will be evident to those who have previously studied the subject that Fritz Müller has been my chief guide in this discussion. We owe much both to Brauer and to Lubbock, but I think that we owe to Müller, and indirectly to his master, Charles Darwin, the most considerable advance in the philosophy of transformation that has been made for two centuries.

L. C. MIALL.

LUDWIG RÜTIMEYER.

THIS distinguished naturalist was born at Biglen, in the Canton Bern, in 1825. His father was the parish clergyman, but was shortly afterwards made superintendent of the Orphanage at Bern. Here Ludwig, when old enough, attended the High School, going when sixteen years of age to the Gymnasium. At this time he made the acquaintance of Bernhard Studer, and with him made several excursions to the surrounding Alps. In 1843 he entered the University of Bern, with the intention of following his father's profession, and for some years devoted himself to theological studies; but all the time he seems to have been more or less attracted to the study of natural history, and, as we believe, partly influenced by the companionship of Peter Merian (the well-known palæontologist of Basel, born 1795), Rütimeyer took up the medical faculty about 1848, and for the rest of his life devoted himself to to the study of comparative anatomy. He soon extended his travels, and we find him in 1850 at Paris, where, among many others, he met Elie de Beaumont. In 1851 he visited the south of France and Italy, going as far as Palmero. In 1852 he came to London, and made the acquaintance of Owen and Murchison. Returning to Bern, he published "Vom Meer bis zu den Alpen," the substance of which he had given as a course of popular lectures. He filled the post of teacher in the Technical School, and seems at this period of his life to have had the not unusual struggle in striving to make both ends meet. He married in 1855, and through the influence of Peter Merian he was appointed to the recently-founded chair of Zoology and Comparative Anatomy at Basel, which post he held until his death, which took place on the 26th of last month.

It is not necessary to give a list—it would be long one—of Rütimeyer's published works. He was scarcely settled at Basel before memoir after memoir came from his pen. One of the earliest, laid before the Natural History Society of Basel, was "On Recent and Fossil Swine," showing then the tendency his thoughts were taking. Perhaps the work by which he will be the longest remembered by, will be "Die Fauna der Pfahlbauten in der Schweiz." In this quarto volume we have a careful series of researches into the natural history of the wild and domestic mammals of Middle Europe, which attracted great attention at the time, from the preciseness of its details and the wideness of its speculations. It was published in 1861, a couple of years after the first publication of "The Origin of Species"; but many of the details had been laid before the Society of Antiquaries of Zürich in the previous year, and the author was fortunate in having the assistance of such investigators as Keller, Morlot, Uhlmann, Troyon, and Forel.

Personally Rütimeyer was extremely amiable; he was a good teacher, after what is now being called the old type; minute investigation he never attempted; he left the microscope to others, beginning his life at the parting of the ways, and interested chiefly with the study of fossil forms, he always remained a morphologist.

NOTES.

THE Paris Academy of Sciences has awarded the Lecomte prize of 50,000 francs to Prof. Ramsay and Lord Rayleigh for their discovery of argon.

THE French Chamber of Deputies has unanimously agreed to refer to the Budget Committee a proposal to contribute to the Pasteur statue. The Committee and the Government will decide on the amount.

IN connection with the visit of the British Association to Liverpool in 1896, meetings of the sub-committees have been held under the presidency of Sir W. B. Forwood and Mr. E. K. Muspratt. The principal result is to make some alterations in the places of meeting of the various sections. It had been arranged that the reception and the central offices should be in St. George's Hall. It has now been arranged that the sections of physics, chemistry, zoology, and physiography shall hold their meetings at University College, that the Town Hall shall be placed at the disposal of the economic section, and that St. George's Hall and the Walker Art Gallery shall be devoted to the remaining sections of geology, engineering, anthropology, botany, &c. It was announced that Prof. J. J. Thomson had accepted the presidency of the mathematics and physics section, while Mr. J. E. Marr will preside over the geologists, and Prof. E. B. Poulton, Hope Professor at Oxford, the section of zoology. The local secretaries hope to be able to publish shortly a complete list of those who have accepted nomination as presidents in the remaining sections.

THE benefactions recently showered upon American educational institutions are bewildering in their multiplicity and munificence. Among the latest reported are several tracts of land purchased near the new site of the University of the City of New York in the annexed district of New York City, and intended for the benefit of that university. Mr. Frederick Baker has paid 35,000 dollars for a lot which he intends to devote to the erection of a hall. Several acres have come into the possession of the Dutch Reformed Church, and on these a church will be

erected, at a cost of 100,000 dollars, for the benefit of the university. Miss Helen Gould, daughter of the late Jay Gould, has purchased several acres on Loring and Oxford Avenues, north-east of the university *campus*, which is supposed to be intended as a site for residences of the professors, as Miss Gould has already shown herself interested in the university by endowing twelve scholarships of 5000 dollars each.

THE eclipse expedition, briefly referred to in our notes last week, left Brooklyn on December 5 for Aleeshi, on the island of Yezo, the northernmost of the Japan group, to observe the total eclipse of August 9, 1896. The schooner-yacht *Coronet*, the largest yacht in the New York Yacht Club, 133 feet long and of 152 tons burden, was generously placed at the disposal of Prof. David P. Todd, of Amherst, by her owners, Mr. D. Willis James and Mr. Arthur C. James. The yacht has already become famous as the winner of 10,000 dollars in a race across the ocean with the yacht *Dauntless*, and she has also already once sailed round Cape Horn, going from New York to San Francisco in 105 days. The same course will be taken now, and the time of the voyage may be shortened. On arrival at San Francisco, she will be joined by Prof. and Mrs. Todd, Mr. Arthur C. James and wife, and a corps of scientific workers, and will then proceed to her destination, after a short stop at Honolulu. The equipment will include about three tons of apparatus, comprising twenty-five or thirty telescopes, both refracting and reflecting, fitted with automatic photographic cameras, which will be set to take 400 or 500 photographs of the corona during the totality of the eclipse. The exposures will be of varying length, from half a second up to several seconds, and will be made with a series of graduated discs, so as to take, in some cases, the entire corona, and in others, outer and fainter portions of it. Almost all the work of observation will be thus photographic, and only a single observer will note appearances through a telescope. Most of the apparatus is already stowed in the yacht. The lenses, however, will be taken overland in the spring, when the party go to embark at San Francisco.

ANOTHER important scientific expedition set out on December 5; for on that day Mr. Frank H. Cushing left Washington for St. Augustine, Florida, where he will be joined by a number of assistants, and the party will sail on a schooner to Pine Island, below Punta Gorda and the southern Florida keys, where a thorough investigation, which is expected to last several months, will be made into the recently discovered mounds built by a remarkable people, who attained a high state of civilisation. Mr. Cushing has already discovered well-preserved remains of the "Shell Age" of prehistoric man. Objects of art made from shell, and shell implements, were found well-preserved, among the most remarkable being a shell pick, still mounted on its original handle of mango wood. The expedition is under the joint auspices of the Ethnographical Bureau of the United States and the Archæological Department of the University of Pennsylvania.

A FURTHER example of the keen interest taken by the German Government in all that concerns the development of trade is reported by the Vienna correspondent of the *Times* as follows: "A newspaper in the Japanese language has recently been published at Yokohama under English auspices. The aim of this journal, for which only a very moderate charge is made, is to familiarise the people of Japan with British merchandise. It appears that Germany has convinced herself of the efficacy of the enterprise, for that Government has lately instructed the Legation and the various Consulates to consider and report upon the methods best suited to ensure the success of a similar undertaking on German lines. It is now stated on good authority that the issue of a German newspaper has been definitely decided upon. It will be edited at the Academy of Oriental Languages in Berlin, and will be printed in Germany and forwarded to Japan for distribution among the inhabitants free of charge." One wonders whether, under similar circumstances, our own Government would have sought the assistance of a learned Society or Academy to carry out its projects.

FROM the same source, we learn that an expedition, fitted out at considerable expense by the Lyons Chamber of Commerce, and entrusted with the mission of thoroughly investigating the trade and commerce of Eastern Asia, has arrived in China. The expedition is exclusively composed of experts, who have undertaken to study the means of developing the trade with the interior, and to open up the wealth of the country to European enterprise. Whatever measure of success may attend their efforts, they will, at all events, traverse districts hitherto wholly unexplored. Finally, it is reported that at the initiative of the Blackburn Chamber of Commerce an English expedition will start shortly to explore the western provinces of Szu-chuan and Yun-nan.

ONE thing after another has cropped up lately to call the attention of the Government and the press to the need for an inquiry into the reason why England is behind Germany and other nations in the industrial applications of science. Mr. J. Powell Williams, who is the Financial Secretary to the War Office, has just had to confess that dried vegetables of various kinds, prepared in a particular manner, and required for the Ashanti Expedition, had to be procured from Germany, as they cannot be obtained in this country. Possibly the Government is under the impression that carrots, potatoes, and turnips cannot be grown in England. For if not, why is not something done to find out how they can be reduced to a dried condition suitable for keeping and transportation? There are dozens of chemists who know the processes by which vegetables can be best prepared for future consumption, and who would be glad to assist in the development of a new British industry.

ON Monday, Lord Herschell gave an address on the work of the Imperial Institute, in reply to some of the criticisms which have been levelled against it. He showed that the collections of economic products from India and the colonies had grown, and had been of some use to merchants and manufacturers; he also mentioned a few investigations that had been carried on under the auspices of the Institute, and described the work of the commercial intelligence department. There is one point, however, upon which we should like to say a word. Lord Herschell remarked that, in accordance with the original scheme, the buildings of the Institute had been applied to the reception of Congresses, such as the International Geographical Congress. This gives the idea that the Council of the Institute granted, without payment, the use of their buildings to the Congress; and if that had been done, we should regard the action as worthy of an Institute which professes to encourage science. But we understand that the International Geographical Committee had to pay a sum of £1100 for the use of the Institute buildings for the Congress, besides several hundreds more in incidental expenses, and that the whole business connected with the hire of the buildings was conducted in a strictly commercial spirit. Lord Herschell omitted this plain statement of fact from his address; but a few transactions of this character are more than sufficient to dispel the belief that the Institute has the promotion of science at heart.

THE Russian correspondent of the *Lancet* has learnt from Prof. Erisman, the general secretary to the Congress, that the date fixed for the next International Medical Congress is the week beginning August 19 and ending August 26 (New Style), 1897. The official announcement will very shortly be sent to the English press. The Emperor has given his Imperial sanction to the Congress, and the Grand Duke Sergi Alexandro-

vitch, the governor of Moscow (and grandson-in-law to Queen Victoria), has granted it his patronage. The nominal president will probably be the Minister of Public Education; the acting president will almost certainly be Prof. Klein, the Dean of the Faculty of Medicine in the University of Moscow. Prof. Erisman, who holds the chair of Hygiene, has, as already stated, been elected general secretary. The meetings of the Congress will be held in the theatres and laboratories of the University Clinique, the so-called *klinitcheski gorodok*, or clinical townlet. Papers and discussions must be in either the French or German language; Russian has been excluded lest the Congress should become national rather than international, and English on the grounds that it is a language little used or understood by other than Englishmen.

ON Monday afternoon, in the Botanical Theatre of University College, London, Prof. Bonney was presented with his portrait by former geological students of the University of Cambridge and of University College, London. A large number of past and present pupils were present, and Mr. J. J. H. Teall occupied the chair as Prof. Bonney's senior pupil. Mr. J. E. Marr referred to the affection and esteem in which Prof. Bonney was held by all his pupils, and Miss Raisin spoke on behalf of the lady students. At the conclusion of her remarks, Prof. W. J. Sollas made the presentation on behalf of the subscribers. The portrait having been unveiled, Prof. Bonney replied. In the course of his remarks he advised those who heard him never, if they could help it, to take things on trust. No doubt books were of great value, but before they trusted them they must know the writers. They must gather facts, and, having done so, take a comprehensive view of them and treat them as inductive. They should not be fascinated by brilliant hypothesis, nor try to write too much; for careless observation and unsound induction were rather a curse than a blessing to science.

DR. J. BATTY TUKE has been elected President of the Royal College of Physicians of Edinburgh.

THE largest battery of dynamite guns in the world was tested recently at San Francisco, and found to work satisfactorily.

WE understand that the Bruce photographic telescope is to be transferred from Harvard University at Cambridge, U.S., to the University station at Arequipa, Peru.

THE Council of the Royal Statistical Society have awarded the Howard medal of 1895 to Mr. John Watson, for his essay on "Reformatory and Industrial Schools."

REUTER reports that Dr. Warth, of the Geological Survey of India, while gold-prospecting in Chota Nagpur, Bengal, struck a reef of remarkable richness. The Indian Government has ordered the erection of stamps for trial crushings.

THE deaths of the following men of science are announced:—Dr. Popoff, Extraordinary Professor of Physiology in the University of Dorpat; Dr. A. de Cerqueira Pinto, formerly Professor of Organic Chemistry in Bahia; Dr. Teichmann, formerly Professor of Anatomy in Cracow.

SURGEON-COLONEL C. ROE, who has been appointed honorary secretary of the Association for the establishment of a Pasteur Institute in India, has made an appeal for funds to ensure the success of the scheme. There is little doubt that the required amount will be collected.

THE two following afternoon lectures will be delivered at the Royal Institution in January, in addition to the arrangements already announced: Dr. A. Donaldson Smith, "To the North of Lake Rudolf and among the Gallas," and Mr. Walter R. Lawrence, C.I.E., on "The Valley of Kashmir."

PROF. W. H. DALL recently returned to Washington from an expedition to examine the coal-fields of Alaska. He found and brought back pieces of fat of a mammoth preserved in ice for ages, being the first discovery of the kind in America. He also discovered a species of bear not previously known to zoologists, but apparently familiar to residents of Alaska, and known there as the ice-bear.

THE Automatic Telephone Company has just been incorporated at Albany, and will construct a new system of telephones, which, as the name implies, are self-acting and independent of any central office. Each subscriber can make and discontinue his own connections by means of an improved device. Tests have already been made, and the system will be at once put in use in New York and Brooklyn.

AN advance copy of Appendix I. 1896, to the *Kew Bulletin* has been sent us. It contains a list of seeds of hardy herbaceous annual and perennial plants and of hardy trees and shrubs which, for the most part, have ripened at Kew during the year 1895. These seeds are not sold to the general public, but are available for exchange with colonial, Indian, and foreign botanic gardens, as well as with regular correspondents of Kew. We hasten to publish this information for the benefit of directors of botanic gardens across the seas. No application, except from remote colonial possessions, can be entertained after the end of March next year.

A TELEGRAM from Captain Roborovsky, dated December 4, announces that the Russian Tibet expedition has finally returned to the Russian dominions, at Zaisan, after having crossed Dzungaria, by two different routes, on their way from the Lyukchun depression. The same telegram announces that the expedition, which has covered nearly 10,700 miles and made a survey of the whole route, and determined the positions of thirty points by astronomical observations, returns heavily laden with natural history collections: 280 specimens of mammals, 1300 of birds, 450 of amphibia and fishes, 30,000 of insects, 25,000 (1300 species) of plants, 300 of seeds, and 300 geological specimens. The meteorological station at Lyukchun has been working for fully two years.

IT is satisfactory to learn that the efforts made by the *Engineer*, to secure the repeal of the existing legal restrictions on the use of mechanical road carriages, are being well supported by many who are taking personal interest in the new vehicle. From a note in the current number of our contemporary, it appears that all the necessary steps have been taken to bring the subject before the notice of the Government; that Mr. Chaplin, as President of the Local Government Board, has expressed himself in strong sympathy with the movement, and that the memorial to him, prepared by the *Engineer*, and signed by leading manufacturing firms and engineers all over the country, has now been placed in his hands. The way for the introduction of a Bill has thus been prepared, and an association has already been formed to support the demand for freedom to use mechanical road carriages equal to that now enjoyed for horse-hauled vehicles.

THE death is announced, in the *Times*, of M. A. P. Kostycher, Director of Agriculture in Russia. M. Kostycher was appointed Professor of Agriculture in 1876, and created the first laboratory in Russia for the study of soils and agricultural products. He held this appointment for seventeen years, in the course of which he made some very interesting researches into the nature and origin of the celebrated "black earth," which is such a source of wealth to the 250,000,000 acres of land in Southern Russia. His six volumes on this subject are regarded as standard works. In 1894 he was appointed assistant to M. Yermolof, who had just been placed at the head of the Agricultural Department. M. Kostycher contributed a very elaborate

chapter to the work on agriculture and forestry, which was published by the Russian Government at the time of the Chicago Exhibition, and was translated into English by Mr. J. M. Crawford, the Consul-General at St. Petersburg.

ACTING upon the report of the Departmental Committee on the Screening of Side Lights of Ships, the Board of Trade have issued the following instructions to their surveyors throughout the country:—The Committee appointed by the Board of Trade under minute of March 18, 1895, to consider the question of the screening of side lights have reported, *inter alia:* (1) That the Order in Council of January 30, 1893, be cancelled. (2) That in the case of oil lamps the forward edge of the screen, or chock on it, should be in a line parallel to the keel with the inside edge of the wick. (3) That in the case of electric lights there should be a similar screening in regard to the inside edge of the filament. (4) That the breadth of the wick of oil lamps, and of the filaments in the case of the electric light, should be not more than two inches, nor less than one inch, measured at right angles to the fore and aft line of the ship. The Board having decided to adopt the above recommendations, the surveyors are informed that the instructions as to the screening of side lights contained in the present issue of "Instructions as to the Survey of Passenger Accommodation, Master's and Crew Spaces," "Lights and Fog-signals," so far as they have either direct or indirect reference to the lights being screened to an angle of convergence of 4° from the outside edge of the wick, are no longer to be put in force, but instead thereof the surveyors are to carry out the directions as to screening contained in above paragraphs, numbered 2, 3, and 4.

THE better protection of wild birds was the object of a deputation that waited upon the Home Secretary on Tuesday. The deputation consisted of members of the eight Councils having an area within the Metropolitan Police district. Mr. Montagu Sharpe said they desired to urge (1) that the close time under Section 8 of the Act of 1880 should be extended; (2) that thirteen new species of birds, in addition to those mentioned in Section 3 of the Act of 1894, should be scheduled; and (3) that the eggs of forty-six species of birds should be scheduled for protection under Section 2 of the Act of 1894. It was desired that the close time for wild birds should be extended to the period between February 1 and August 31. The birds which it was sought to add to the list were the wryneck (cuckoo's mate, or snake-bird), swallow, martin (2), swift, bearded tit (reedling and reed pheasant), kestrel, merlin, hobby, buzzard, honey buzzard, osprey, magpie, and shrike. These birds should be protected not only for their beauty, but for their usefulness in destroying noxious insects, mollusca, and rodents, which were particularly destructive in suburban gardens. The Home Secretary expressed agreement with the proposals of the deputation, and said he would comply with their desire with regard to the scheduling of birds and their eggs.

AN improvement on the simple pendulum for purposes of measurement is described by G. Guglielmo in the *Atti dei Lincei.* The simple pendulum oscillates about its point of suspension in all directions. The compound pendulum rests on a knife-edge, or essentially on two points some distance apart, and therefore oscillates always in the same plane. A bob suspended by two threads will do the same, and will have the additional advantage of simplicity. But for some purposes it is highly desirable to have a body oscillating in the same plane, and parallel to itself. Sgr. Guglielmo has accomplished this by taking two such bifilar pendulums and joining them by a horizontal rod placed in their plane of vibration. This contrivance can be used for a variety of purposes. An electrometer is described in which the rod is replaced by a small cylinder moving inside another, and displaced by any difference of potential between the two. A very useful application of it is the anemometer designed on this plan. A vertical disc is fixed on one end of the rod, and exposed directly to the wind. Wild's anemometer, which consists of a simple plate, the inclination of which alters with the strength of the wind, does not give the horizontal velocity of the wind in a simple manner. The new anemometer always exposes a vertical disc to the wind, and the force is directly given by the deflection of the suspending wires. It should be mentioned that the suspending wires are of iron, joined to the rod and to the supports by short lengths of silk thread to ensure flexibility. Many interesting investigations may be carried out with this apparatus: the influence of the inclination of the disc may be studied, and the indications of Robinson's revolving anemometer may be verified. Oscillations are effectively damped by a wire attached to the rod with a disc attached to its lower end and immersed in water.

WITH the scientific intelligence in the December number of the *American Journal of Science,* we find the following note on underground temperatures at great depths, received by the editors from Prof. A. Agassiz:—"For several years past I have, with the assistance of our engineer, Mr. Preston C. F. West, been making rock temperature observations as we increased the depth at which the mining operations of the Calumet and Hecla Mining Company were carried on. We have now attained at our deepest point a vertical depth of 4712 feet, and have taken temperatures of the rock at 105 feet, at the depth of the level of Lake Superior, 655 feet, at that of the level of the sea, 1257 feet, at that of the deepest part of Lake Superior, 1663 feet, and at four additional stations, each respectively 550, 550, 561, and 1256 feet below the preceding one, the deepest point at which temperatures have been taken being 4580 feet. We propose, when we have reached our final depth, 4900 feet, to take an additional rock temperature, and to then publish in full the details of our observations. In the meantime it may be interesting to give the results as they stand. The highest rock temperature obtained at the depth of 4580 feet was only 79° F.; the rock temperature at the depth of 105 feet was 59° F. Taking that as the depth unaffected by local temperature variations, we have a column of 4475 feet of rock with a difference of temperature of 20° F., or an average increase of 1° F. for 223·7 feet. This is very different from any recorded observations; Lord Kelvin, if I am not mistaken, giving as the increase for 1° F., fifty-one feet, while the observations based on the temperature observations of the St. Gothard tunnel gave an increase of 1° F. for sixty feet. The calculations based upon the latter observations gave an approximate thickness of the crust of the earth, in one case of about twenty miles, the other of twenty-six. Taking our observations, the crust would be over eighty miles, and the thickness of the crust at the critical temperature of water would be over thirty-one miles, instead of about seven, and 8·5 miles as by the other and older ratios. With the ratio observed here, the temperature at a depth of nineteen miles would only be about 470°, a very different temperature from that obtained by the older ratios of over 2000° F. The holes in which we placed slow registering Negretti and Zambra thermometers were drilled, slightly inclined upward, to a depth of 10 feet from the face of the rock, and plugged with wood and clay. In these holes the thermometers were left from one to three months. The average annual temperature of the air is 48° F., the temperature of the air in the bottom of the shaft was 72° F."

THE first part of a cheap edition of "Science for All" has just been published by Messrs. Cassell and Co. So far as we can see, few revisions have been made; hence the work in nowise represents the state of scientific knowledge at the present time.

UNDER the title, "Neue Gedanken zur Vererbungsfrage," the original German text of the article by Dr. Weismann in the *Contemporary Review* for September, has been published by Gustav Fischer, Jena. The article was a reply to one by Mr. Herbert Spencer, in the *Contemporary* of October 1894, and was written at the beginning of this year; but the time taken to translate it into English caused its publication to be delayed until September.

THE Cambridge University Press will publish in a few weeks a comprehensive work on "Ethnology," by Prof. A. H. Keane. The work is divided into two parts, the first dealing with those fundamental problems which affect the human family as a whole, the second discussing those general questions which concern the primary human groups. Evolutionary principles are taken as the basis of construction throughout the work.

THE "Live Stock Journal Almanac" for 1896 has been published by Messrs. Vinton and Co. It contains an abundance of information on all points connected with the breeding and management of live stock, and is plentifully illustrated. Among the articles we notice "Feeding Pastures," by Mr. W. Carruthers, F.R.S.; "Factors in Horse Breeding," by Captain M. H. Hayes; and "Four Feathered Friends," by Mr. A. F. Lydon. The last-named article will do good by showing agriculturists the usefulness of the linnet, chaffinch, goldfinch, and yellow-hammer.

SEVERAL valuable papers on fruit-growing appear in the *Journal* of the Royal Horticultural Society (vol. xix. part 2, November). M. Charles Baltet, President of the French Pomological Congress, describes the principal points connected with the cultivation of fruit in France, and enumerates the principal varieties recommended to fruit-growers, whether amateurs cultivating for home consumption, or farmers for commercial purposes. At a conference held in September, Mr. G. Bunyard described a number of fruits recently brought to the front; Mr. A. H. Pearson gave a paper on pruning fruit-trees; and a prize essay on the commercial aspect of hardy fruit-growing was read. It may be remembered that in the early spring of this year, the Society offered a prize of £10 for the best essay on this subject. Two essays were selected as of equal merit, and the prize, increased by £5, was divided between the authors, Mr. Lewis Castle and Mr. S. T. Wright. Both these essays are printed in full in the *Journal* before us, and we have no doubt that they will give an effective impulse to the cultivation of fruit in this country.

THE additions to the Zoological Society's Gardens during the past week include a Moor Monkey (*Macacus maurus*, ♀) from the East Indies, presented by Mr. Granville Bantock; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mr. Charles Henderson; three American Jabirus (*Mycteria americana*) from the Island of Marajo, North Brazil, presented by Mr. H. A. Astlett; a Spotted Eagle Owl (*Bubo maculosa*) from East Pondoland, South Africa, presented by Mr. R. W. Murray; a Woodcock (*Scolopax rusticula*), British, presented by Mr. Charles Smoothy; two Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Mr. J. Palmer; a Hoary Snake (*Coronella cana*) from South Africa, presented by Mr. J. E. Matcham; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, a Leopard Tortoise (*Testudo pardalis*) from South Africa, deposited; a Black-necked Stilt Plover (*Himantopus nigricollis*) from South America, nine Long-eared Sun Fish (*Lepornis auritus*), five Rock Bass (*Ambloplites rupestris*), six Catfish (*Amiurus catus*) from North America, a Reeves's Terrapin (*Clemmys reevesi*) from China, two Red-headed Pochards (*Fuligula cerina*), European, purchased.

OUR ASTRONOMICAL COLUMN.

COMETS BROOKS AND PERRINE.—The following ephemeris for Comet Brooks, for Berlin midnight, is by Dr. Berberich (*Ast. Nach.*, 3321):—

	R.A. h. m. s.	Decl. ° ′
Dec. 19	5 8 5	+67 59·0
20	4 50 45	68 27·9
21	34 19	68 47·3
22	18 56	68 58·9
23	4 4 39	69 4·2
24	3 51 30	69 4·5
25	39 29	69 0·9
26	3 28 33	+68 54·2

Comet Perrine is now moving northwards, and is becoming more favourably placed for observation, as shown in the following extract from Dr. Lamp's ephemeris for Berlin midnight (*Ast. Nach.*, 3322):—

	R.A. h. m. s.	Decl. ° ′	Brightness.
Dec. 19	18 31 25	−30 18·4	57·0
20	43 16	29 16·0	
21	52 14	28 6·0	35·3
22	18 59 0	26 55·6	
23	19 4 8	25 47·3	20·4
24	8 6	24 42·6	
25	11 16	23 42·1	12·3
26	19 13 53	−22 45·4	

The brightness on November 18 is taken as unity.

A NEW OBSERVATORY.—We learn from *Science* that the Legislature of Minnesota has granted £2000 for the erection of a student's observatory at the University of Minnesota. The building is already under roof, and is promised for use by January 1, 1896. The equipment will include a 10-inch equatorial of 150 inches focal length. This instrument is to have a triple objective, one combination of which will form the visual telescopic objective, and another the photographic objective. A spectroscope and photograph measuring machine are among the accessories soon to be added. Upon the completion of this working observatory, Prof. Leavenworth will use it to carry on advanced instruction in astronomy.

PHOTOGRAPHY OF MINOR PLANETS.—Dr. Max Wolf, who has taken a prominent part in the detection of new minor planets by the trails which they leave on a photographic plate during a long exposure, describes his method of work in some detail in *Ast. Nach.*, 3319. His photographic telescope consists of a 6-inch portrait lens of 30 inches focal length, and giving a field of about 70 square degrees. In order to distinguish between true planetary trails and defects of the plates, two photographs of each region are taken, the necessary exposures usually not being more than two hours. One of the best methods of detecting differences between two photographs of the same region is to compare a positive with a negative, the films being in contact; the two trails will then be seen in continuation of each other if they are real. Another method of detecting the trails readily is to employ a stereoscope for viewing the two photographs, the change of position bringing out the planet in relief. As might be expected from the instrument employed, measurements of the photographs do not furnish positions with any great degree of accuracy, but they serve as a guide to observers using instruments of greater precision.

It is somewhat remarkable that Dr. Wolf has not telescopically observed any one of the numerous planets which he has discovered by the photographic method.

SHORT PERIOD VARIABILITY.—The recent researches on the spectra of short-period variable stars, more especially of δ Cephei, have no doubt led many to inquire into the possible explanations of the phenomena observed. Among others, Mr. A. W. Roberts, an assiduous observer of this type of variable in the southern hemisphere, has given attention to the subject (*Astrophysical Journal*, November, p. 283). Omitting the Algol variables, which are perhaps sufficiently explained by eclipses, and β Lyræ, which may provisionally be considered as a special case, any satisfactory theory must explain the relative rapidity of the rise to maximum, continuity of variation throughout the period, and the small range of the light changes. In the case of δ Cephei, Belopolsky has shown that the variability is intimately connected with its revolution, the star being apparently

associated with a relatively dark body; and it is perhaps allowable to suppose a similar connection in the case of other variables of the same class. Besides the possibility of eclipses, this orbital movement may operate in two other ways to produce light changes. If the companion be a dark body, there will be phases depending upon its varying reflection of light from the primary, but the changes of magnitude due to this cause will be practically negligible. When the orbit is very eccentric, as in δ Cephei, the temperature of the companion will vary very considerably at different parts of the revolution, and Mr. Roberts seems to regard its consequent changes of brightness as probably the main cause of the variability. It is admitted, however, that the variations of 1·5 or 2 magnitudes, which are occasionally met with, cannot be satisfactorily explained in this way, and it is necessary to suppose an additional variation of the primary itself due to disturbances at periastron. In the variables, like η Aquilæ, which show a secondary minimum, it is only necessary to suppose that an eclipse also takes place. Attention is drawn to two tests of this theory. First, the companion should show itself spectroscopically at the quadrature following periastron; second, telescopic double stars having highly eccentric orbits should exhibit fluctuations of magnitude depending upon the distance between the components. It should be remembered that there is as yet no evidence of luminosity of the companion to δ Cephei, but it may be that the exposures given to the spectrum photographs have been insufficient to depict it.

THE NEW MINERAL GASES.[1]

As Mr. Crookes has now published (*Chemical News*, August 23, 1895), the wave-lengths of the lines in the spectra of the new mineral gases observed by him in the tubes supplied by Prof. Ramsay, I propose in the present paper to bring together some notes I have made (some of them some time ago) on the same subject.

The researches made at Kensington in connection with the new gases obtained from bröggerite and other minerals has consisted, to a large extent, of comparisons of the lines in their spectra with lines in the spectra of the sun and stars. Preliminary accounts of these comparisons have already been given, and they show that the bright yellow line seen in the gas from bröggerite is by no means the only important one which appears.

Although the general distribution and intensities of the lines in the gases from bröggerite and cleveite sufficiently corresponded with some of the chief "unknown lines" in the solar chromosphere and some of the stars to render identity probable, it was desirable to see how far the conclusion is sustained by detailed investigations of the wave-lengths of the various lines.

The Yellow Line λ 5875·9.—Immediately on receiving from Prof. Ramsay, on March 28, a small bulb of the gas obtained from cleveite, a provisional determination of wave-length was made by Mr. Fowler and myself, in the absence of the sun, by micrometric comparisons with the D lines of sodium, the resulting wave-length being 5876·07 on Rowland's scale. It was at once apparent, therefore, that the gas line was not far removed from the chromospheric D_3, the wave-length of which is given by Rowland as 5875·98.

The bulb being too much blackened by sparking to give sufficient luminosity for further measurements, I set about preparing some of the gas for myself by heating bröggerite *in vacuo*, in the manner I have already described. A new measurement was thus secured on March 30 with a spectroscope having a dense Jena glass prism of 60°; this gave the wave-length 5876·0.

On April 5, I attempted to make a direct comparison with the chromospheric line, but though the lines were shown to be excessively near to each other, the observations were not regarded as final.

Prof. Ramsay having been kind enough to furnish me, on May 1, with a vacuum tube which showed the yellow line very brilliantly, a further comparison with the chromosphere was made on May 4. The observations were made by Mr. Fowler, in the third order spectrum of a grating having 14,438 lines to the inch, and the observing telescope was fitted with a high power micrometer eye-piece; the dispersion was sufficient to easily show the difference of position of the D_3 line on the east and west limbs, due to the sun's rotation. Observations of the chromosphere were therefore confined to the poles.

During the short time that the tube retained its great brilliancy, a faint line, a little less refrangible than the bright yellow one, and making a close double with it, was readily seen; but afterwards a sudden change took place, and the lines almost faded away. While the gas line was brilliant, it was found to be "the least trace more refrangible than D_3, about the thickness of the line itself, which was but narrow" ("Observatory Note Book"). The sudden diminution in the brightness of the lines made subsequent observations less certain, but the instrumental conditions being slightly varied, it was thought that the gas line was probably less refrangible than the D_3 line by about the same amount that the first observation showed it to be more refrangible. Giving the observations equal weight, the gas line would thus appear to be probably coincident with the middle of the chromospheric line, but if extra weight be given to the first observation, made under much more favourable conditions, the gas line would be slightly more refrangible than the middle of the chromosphere line.

Pressure of other work did not permit the continuation of the comparisons. In the meantime, Runge and Paschen announced (NATURE, vol. lii. p. 128) that they also had seen the yellow line of the cleveite gas to be a close double, neither component having exactly the same wave-length as D_3, according to Rowland. They give the wave-length of the brightest component as 5878·883, and the distance apart of the lines as 0·323.

This independent confirmation of the duplicity of the gas line led me to carefully re-observe the D_3 line in the chromosphere for evidences of doubling. On June 14 observations were made by Mr. Shackleton and myself of the D_3 line in the 3rd and 4th order spectra under favourable conditions; "the line was seen best in the 4th order, on an extension of the chromosphere or prominence on the north-east limb of the sun. The D_3 line was seen very well, having every appearance of being double, with a faint component on the red side, dimming away gradually; the line of demarcation between the components was not well marked, but it was seen better in the prominence than anywhere else on the limb" ("Observatory Note Book").

It became clear, then, that the middle of the chromosphere line, as ordinarily seen, and as taken in the comparison of May 4, does not represent the place of the brightest component of the double line, so that exact coincidence was not to be expected.

Though the observations are not yet quite completed, the circumstance that the line is double in both gas and chromosphere spectrum, in each the less refrangible component being the fainter, taken in conjunction with the direct comparisons which have been made, render it highly probable that one of the gases obtained from cleveite is identical with that which produces the D_3 line in the spectrum of the chromosphere.

Other observers have since succeeded in resolving the chromospheric line. On June 20, Prof. Hale found the line to be clearly double in the spectrum of a prominence, the less refrangible component being the fainter, and the distance apart of the lines being measured as 0·357 tenth-metres (*Ast. Nach.*, 3302).

The doubling was noted with much less distinctness in the spectrum of the chromosphere itself on June 24. Prof. Hale points out that Rowland's value of the wave-length (as well as that of 5875·924, determined by himself on June 19 and 20) does not take account of the fact that the line is a close double.

Dr. Huggins, after some failures, observed the D_3 line to be double on July 10 (*Ast. Nach.*, 3302); he also notes that the less refrangible component was the fainter, and that the distance apart of the lines was about the same as that of the lines in the gas from cleveite, according to Runge and Paschen.

It may be added, that in addition to appearing in the chromosphere, the D_3 line has been observed as a bright line in nebulæ by Dr. Copeland, Prof. Keeler, and others; in β Lyræ and other bright line stars; and as a dark line in such stars as Bellatrix, by Mr. Fowler, Prof. Campbell, and Prof. Keeler. In all these cases it is associated with other lines, which, as I shall show presently, are associated with it in the spectra of the new gases.

The Blue Line, λ 4471·8.—A provisional determination on April 2 of the wave-length of a bright blue line, seen in the spectrum of the gases obtained from a specimen of cleveite,

[1] "On the New Gases obtained from Uraninite. (Sixth Note.)" By J. Norman Lockyer, C.B., F.R.S. Received at the Royal Society, September 10, read November 21.

showed that it approximated very closely to a chromospheric line, the frequency of which is stated as 100 by Young.

This line was also seen very brilliantly in the tube supplied to me by Prof. Ramsay on May 1, and on May 6 it was compared directly with the chromosphere line by Mr. Fowler. The second order grating spectrum was employed. The observations in this region were not so easy as in the case of D_3, but with the dispersion employed, the gas line was found to be coincident with the chromospheric one. In this case also, the chromosphere was observed at the sun's poles, in order to eliminate the effects due to the sun's rotation.

In a former note (*Roy. Soc. Proc.*, vol. lviii. p. 114), I have pointed out that this line does not appear in the spectra of the gases obtained from all minerals which give the yellow line.

Besides appearing in the spectrum of the chromosphere, the line in question is one of the first importance in the spectra of nebulæ, bright line stars, and of the white stars such as Bellatrix and Rigel.

The Infra-red Line, λ 7065·5.—In addition to D_3 and the line at 4471·8, there is a chromospheric line in the infra-red which also has a frequency of 100, according to Young. On May 28, I communicated a note to the Royal Society stating that this line had been observed in the spectrum of the gases obtained from bröggerite and euxenite (*Roy. Soc. Proc.*, vol. lviii. p. 192), solar comparisons having convinced me that the wave-length of the gas line corresponded with that given by Young; and I added, "it follows, therefore, that besides the hydrogen lines, all three chromospheric lines in Young's list which have a frequency of 100 have now been recorded in the spectra of the new gas or gases obtained from minerals by the distillation method."

M. Deslandres, of the Paris Observatory, has also observed the line at 7065 in the gas obtained from cleveite (*Comptes rendus*, June 17, 1895, p. 1331).

Other Lines.—Determinations of the wave-lengths of many other lines in the spectra of the new gases have been made, chiefly with the aid of a Steinheil spectroscope having four prisms, and the results leave little doubt as to the coincidence of several lines with those appearing in the chromosphere, nebulæ, and white stars.

It seems very probable, also, that many lines which have been noted, and for which no origins have yet been traced, belong to gases which have not hitherto been recorded in the chromosphere.

The following table summarises the chief lines which have so far been recorded in the new gases from various minerals, some of which show D_3 while others do not. Only those lines which also appear in the spectrum of the chromosphere, nebulæ, or Orion stars, are given in the first instance. There are other lines which are probably also associated with chromospheric ones, but further investigation of them is considered desirable before they are included in the list.

Wave-length (Rowland).	Wave-length (Angström).	Chromosphere (Young).	Eclipses 1893. Max. intens. = 10.	Orion nebula. Max. intens. = 6.	Bellatrix. Max. intens. = 6.	Crookes' measures.

* Prof. Young has recently called attention to the fact that although this line was not included in his chromospheric list, he observed and published it in 1883; its frequency is about 15. (NATURE, vol. lii. p. 458.)

† This line is too close to a hydrogen line to enable a definite statement to be made.

The first column of the table gives the wave-lengths of the lines on Rowland's scale, while the second gives the wave-lengths on Ångström's scale; the third gives the frequency of the lines in the chromosphere according to Young. In the fourth column lines photographed with the prismatic camera during the total eclipse of April 16, 1893, are shown; these have been included because in some cases lines which appear to be comparatively unimportant in Young's list were photographed as important lines. The fifth column indicates probable coincidences with lines in the spectrum of the Orion nebula; the accuracy of these wave-lengths is of necessity less than in the case of the chromosphere; with the exception of D_3 they are taken from my paper on the photographic spectrum of the Orion nebula (*Phil. Trans.*, 1895, vol. 186A, p. 76). The sixth column shows probable coincidences with dark lines in the spectrum of Bellatrix, this being taken as an example of the Orion stars (*Phil. Trans.*, 1893, vol. 184A, p. 695), the lines 4922·3 and 5015·8 have been photographed since the date of the paper to which reference is made.

The last column gives the wave-lengths, from Mr. Crookes' table, of the lines observed by both of us.

THE DUKE OF DEVONSHIRE ON EDUCATION.

WITHIN the past few days, the Duke of Devonshire has delivered several orations on educational topics. Two of these addresses appeal especially to those who are interested in technical and scientific education: one was delivered at the annual meeting of the National Association for the Promotion of Technical and Secondary Education, to representatives of technical educational committees of county and borough Councils; and the other was a speech to students at the Birmingham Municipal Technical School. We print extracts from the *Times* reports of both addresses, taking them in the order in which they were delivered. To the conference arranged by the National Association, the Duke of Devonshire said:—

It was originally proposed to hold the conference in July, but that was prevented by the occurrence of the general election. While the general election was responsible for the postponement of the conference, it has also had the effect of converting your president from a private individual, entirely irresponsible, whose saying and doings were entirely his own and committed no one, into a member of the Government, who is responsible both to his colleagues and to Parliament. He happens to be not only a member of the Government, but the person who, with my friend Sir John Gorst, is chiefly charged with the direction of educational questions, and also with the administration of large funds, which are administered by the Science and Art Department as well as the Education Department, and he who, therefore, is concerned with technical and secondary as well as elementary education. This change in the position of your president has occurred at a moment when public attention has been very urgently and earnestly directed both to the question of elementary education, which, in the opinion of some persons, has begun to some extent to trespass upon ground that properly belongs to secondary education, and also by the publication of the report of the Royal Commission on Secondary Education.

We have in the report of the Commission a general review of the history of secondary education in this country, of its present position, and suggestions for its future guidance. Great pains have been taken by the Executive Committee of this Association to give in their journal a trustworthy summary of the work which has thus been undertaken by the County Councils. It will be seen that the plans which have been adopted vary greatly in different counties, and while it is most desirable that the special character of each locality should be considered and a wide scope should be given to experiments, and while not even mistakes and some waste of money inseparable from experimental procedure need be wholly regretted, it has been thought that the time has now come when a more uniform system may be encouraged and adopted. In conclusion, I think I may say that, without attempting to anticipate how soon or how completely it may be in the power of any Government to ask Parliament to consider in a more full and comprehensive manner the organisation of secondary education, including technical instruc-

tion throughout the country, it must be recognised that a great deal of work is at present being done, some of which, we may hope, is of very high practical utility, and all of which is of the highest experimental value. That work is being carried on by local and representative authorities, and it cannot but be an advantage that those who are engaged in it should avail themselves of the opportunity now afforded to them of conference and consultation with each other, and thus finding some of the guidance which, under a more completely and thoroughly organised system, they might possibly look for from some central authority.

On Friday last, the Duke of Devonshire opened the new buildings of the Municipal Technical School at Birmingham, and, in the evening of the same day, he distributed the prizes to students in the school, and delivered an address. The following is a condensed report of his remarks:—

The first question which perhaps may occur to some of you is, "Why am I here at all; why am I selected to address this great meeting?" I have been told before to-day, and I have been told again to-night by the Mayor, that it is as President of the Council and head of the Education Department that I am here. I need scarcely tell you that in the somewhat remarkable arrangements which control appointment to the great political offices it does not follow at all that because a politician is appointed to be the head of the Education Department he should know anything whatever about education. The fact that I hold that office and that others have held that office before me who know as little about education as I do, must convince you that the mere fact of my holding that office does not confer upon me any special qualification for the part I am expected to take to-night, and I am afraid before the conclusion of my address some of you may be reminded of the lines of the poet Pope, who, in speaking of the presence of flies in amber, said:—

> "The things, we know, are neither rich nor rare,
> But wonder how the—something—they got there."

I know no more of science or of art than could be put into the capacity of a couple of nutshells, but every member of Parliament is supposed to know something about education. Unfortunately for my own peace of mind, upon one occasion, some years ago now, I happened to be called upon to distribute prizes at a polytechnic institute in London, where I made some observations upon what I thought was an urgent and growing necessity for a greater amount of attention being paid to the scientific and technical education of our people, which appeared to attract some considerable attention. On the strength, I believe, of that speech, I was asked to assume the post of president of a national association for the promotion of technical and secondary education, and since that unhappy moment my life has been more or less a burden to me, and I have been called upon on more occasions than I care to remember to deliver some observations upon subjects of a scientific and an educational character.

It does not require a scientific or educational expert to show that the work which has been done and is being done and is going to be done here is part of a work which is going on all over the country, and which it is for the working population of this country to take or to leave as they please, but it is a work which it is necessary should be done if we intend to maintain not only the industrial supremacy which we have hitherto enjoyed, but even our existence as a great industrial nation. Even upon such a subject as this I can pretend to speak with no authority. All that I have done upon former occasions and all that I can do now is to refer to what has been said by those who can speak upon such a subject with greater authority than I can. Prof. Huxley was one of those who have taken a lead in this movement for the extension of scientific and technical training. These words of his have been quoted before in this hall, but I shall make no excuse to you for quoting them again. He said:—"We are at present in the swim of one of those vast movements in which, with a population far in excess of that which we can feed, we are saved from a catastrophe through the impossibility of feeding them solely by our possession of a fair share of the markets of the world, and in order that that fair share may be retained it is absolutely necessary that we should be able to produce commodities which we can exchange with food-growing people, and which they will take rather than those of our rivals, on the ground of their greater cheapness or their greater excellence. That is the whole story. Our course, let me say, is not actuated by mere motives of ambition or by mere motives of greed. Those, doubtless, are visible enough on the surface of these great movements, but the movements themselves have far deeper sources. Our sole chance of succeeding in the competition which must constantly become more and more severe is that our people shall not only have the knowledge and the skill which are required, but that they shall have the will and the energy and the honesty without which neither knowledge nor skill can be of any permanent avail."

I should like to add a commentary on those words which was supplied, also, I think, on an occasion similar to this, by Sir Henry Roscoe, who has taken a distinguished and a leading part in this movement. Having quoted those words of Prof. Huxley which I have read, Sir Henry Roscoe said: "This great endeavour to place our population in a position to obtain the industrial supremacy which it has long held and to ensure that supremacy is surely of more fundamental importance than any passing political question of the day. Upon the successful solution of this problem depends our very national existence. Pressed on all sides by the superior scientific education of Germany, by the boundless physical resources and indomitable energy of America, we in this country should have enough to do to hold our own in the coming struggle for existence. Hitherto we have rested content with that pre-eminence which our coal and our iron, our insular position, the energy and capability of our race, have given us; such a state of contentment is at the present time a delusion and a snare. We can afford no longer to live in a false paradise. Our competitors have adopted our industrial methods; they have bought our machinery, and are now not only treading on our heels but are surpassing us. Our competitors have adopted our own discoveries and inventions, and are, as it were, working out our own designs. Watt, Stephenson, Arkwright and Crumpton, Whitworth and Bessemer, have made the world akin in more senses than one. Rapid and cheap transit has revolutionised commerce and industry, and raw materials flow in and finished products flow out, and it is to the nation as well as to the men which furnishes that finished article most cheaply and best that victory comes. This, then, is the meaning of technical and industrial training—to fit our people from top to bottom, from the future leader of industry to the lowest handworker, with the means, so far as education can do so successfully, to carry out his life's work. This is the great task we have set ourselves to accomplish." I ask you whether in your opinion this language is exaggerated. I do not think that any man of business who is present here this evening will deny the increasing strain of the competition to which we are exposed. He may not accept the remedies which we suggest, but he will not deny the existence of a danger which we fear.

No one, I think, can doubt the closeness of the connection in the present day between science and industrial pursuits—scientific discovery on the one hand and mechanical invention on the other. These are the factors of industrial progress in this or in any other country. Scientific discovery has made known to us the new properties and qualities of matter; and mechanical invention, on the other hand, has applied those discoveries to industrial processes. How can we expect that our nation can take full advantage of those discoveries; how can we expect that we can satisfy the wants of the world which expects to be put in instant possession of all the advantages of these successful discoveries, unless we have trained managers and foremen who are competent to take instant advantage of every one of those discoveries in science or mechanical invention and possess the scientific skill to apply them; and how can we obtain these managers and foremen unless we place within the reach of the great masses of our people and of our working men facilities for acquiring that scientific knowledge? I may further ask you, can these managers and foremen themselves expect to make the most of their own abilities without the assistance of workmen whose eye and whose hand and whose intelligence have been properly trained to carry out their instructions?

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—For many years the annual reports of the University Extension Delegacy have recorded steady progress in the work committed to its supervision. The report just issued shows that, from September 1894 to May 1895, 1544 lectures were delivered in connection with the Delegacy. The

umber of courses organised by Local Committees showed an increase over those of previous years, but the courses given in connection with County Councils showed a decline. This is because the County Councils have appointed lecturers of their own to carry on the work of the Extension lectures; and because fixed colleges or institutes are taking the place of peripatetic teaching. Oxford centres have never shown a preference for courses of lectures on science subjects: in 1894–95, 142 courses were delivered on history, literature, economics, and art, and fifty-seven courses on various branches of science. That the lectures delivered under the auspices of the Delegacy appeal to a large class is shown by the fact that the aggregate of average attendances during the year covered by the report was 20,809.

MR. HENRY A. MIERS, of the Department of Minerals in the British Museum, has been elected Waynflete Professor of Mineralogy, in place of Prof. Story Maskelyne, resigned.

THE following are among recent appointments abroad: Dr. P. Ehrlich to be Professor of Special Pathology and Therapeutics in the Berlin University. Dr. Janny, *privat-docent* in Surgery, at Budapest, to be Professor; Dr. J. Nevinny to be Ordinary Professor of Pharmacology at Innsbruck; Dr. K. A. Bier to be Extraordinary Professor of Surgery at Kiel; Dr. A. Monti to be Professor of General Pathology at Palermo; Dr. Augustin to be Extraordinary Professor of Meteorology in the Bohemian University at Prague.

THE *Times*, in some noteworthy remarks upon the Duke of Devonshire's Birmingham speech, pointed out the importance of technical education, and the necessity for instruction in fundamental principles. "The people perish for lack of knowledge," remarked our contemporary, "but it is primarily general knowledge that they require. Only upon that foundation can technical knowledge be built up with any chance of obtaining its full advantages. . . . Too much stress cannot be laid upon the cardinal importance of equipping our industrial population with the knowledge which at present is far more copiously and systematically provided by other nations than by ourselves. Indeed, we may question whether even among educational reformers full recognition has yet been given to the fact that time and energy are limited quantities. Is it enough to superadd technical education to a stereotyped course of verbal study? Do we not, in that way, not only waste time which might be much better employed, but postpone the acquirement of manual dexterities to too late a period? It is worth serious consideration whether what is wanted for an industrial population at the present day is not an education essentially technical and practical from a very early age, with the verbal training that now passes for education relegated to a secondary place."

THOUGH in recent years there has been a development of facilities for science instruction for boys, and methods of instruction are slowly being improved, the same kind of advances have not been made in girls' schools. This deficiency was discussed at a meeting held at the Hugh Myddelton School last week, when a paper on "Science Teaching for Girls," was read by Mr. Heller, and the essential points of sound teaching of science were dwelt upon. It was pointed out that the teaching of scientific method rather than the teaching of science subjects should be made a valuable educating factor in all schools; that all such teaching must follow the lines of an investigation, must be accurate and quantitative, and must have a logical sequence; that the scholars must be taught to help and think for themselves, and that the teacher should act rather as an exhaust pump than as a force pump, in extracting facts from the child's brain rather than supplying them. Mr. Heller then sketched a syllabus and scheme of work he is carrying out both with classes of teachers and children in East London, where all facts are discovered by experiment, and nothing is given on the *ipse dixit* of the teacher. Referring to the pioneer work the London School Board is carrying out in the training of teachers, the lecturer proposed the following resolution: "That in the opinion of this meeting the time has arrived when the teaching of scientific method should be made an educating influence in girls' schools, and that such teaching must be of an experimental and investigating nature." In the discussion that followed, Dr. Gladstone urged that all knowledge should be gained by scientific methods, and that no special subjects should be taught even in the higher standards of elementary schools, but rather fundamental principles. Dr. Armstrong thought the time was ripe for great changes. In every direction educational authorities were adopting such work as they had heard described. There was no necessity to teach science, but to form character by teaching scientific methods. He advocated the teaching of mental drill and mental discipline, and in conclusion seconded the resolution, which was carried unanimously.

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 11.—Emissivity of bodies at high temperatures, and the Auer burner, by Ch. E. St. John. The Auer burner only shows very slight fluorescence and phosphorescence. A thin sheet of oxide on electrically-glowed platinum foil does not assume the temperature of the platinum. The emissivities of glowing bodies are best compared by introducing them into a stove whose walls are at a uniform temperature. The oxides composing the Auer incandescent gas-burner show a high emissive power, which, together with its small mass, large surface, and low conductivity, accounts for its efficiency as an illuminant.—The true surface tension of pure water between 0° and 40° C., by P. Volkmann. This was determined by capillary tubes, and controlled by similar observations upon toluol and benzol. Under a pressure of 750 mm. of moist air, the surface tension of pure water was found to be 7·683 mg. per mm. at 0°, 7·543 at 10°, and 7·236 at 30° C.—Condensation of vapours, by Mathias Cantor. The capillary constants of a surface exert a decided influence upon the dew-point of a vapour in contact with it. The author allowed steam to condense on a thin sheet of petroleum spread on mercury. As soon as the thickness of the layer so deposited is equal to the radius of molecular action, the dew-point and the temperature of saturation become the same. This radius was calculated from the results obtained, and was found to be $6{\cdot}5 \times 10^{-6}$ mm., or slightly less than that found by Reinold and Rücker from soap-bubbles.—Relation between the dielectric constant of a gas and its chemical valency, by Robert Lang. This is an important new law connecting the specific inductive capacity of a gas with its chemical valency. Whatever the nature of the gas, its (sp. ind. capacity − 1) increases directly as the total valency of the atoms constituting its molecules. This difference from unity is called by the author the "electrification number," since it indicates the difference of behaviour in the dielectric ether due to the presence of matter. The electrification numbers of H, O, CO, and CO_2 are very nearly as 1 : 2 : 3 : 4.—Dielectric constants of liquefied gases and the Mossotti-Clausius formula, by F. Linde. These constants of liquefied CO_2, Cl, and N_2O were determined by means of the electric oscillation method. On plotting the calculated and observed values different curves were obtained, and it was evident that the spec. ind. capacity depends upon other conditions besides density.—Circular magnetisation of iron wires, by I. Klemencic. When a current traverses an iron wire, the molecules tend to arrange themselves in circular chains round the axis. This gives rise to strong extra currents at break. The magnetic susceptibilities are different along and round the axis. In soft iron the former exceeds the latter, whereas in Bessemer steel the circular susceptibility is the greater.

IN the number of the *Nuovo Giornale Botanico Italiano* for November, Sigr. M. A. Mirabella has an interesting paper in which he describes the extra-floral nectaries of various species of *Ficus* cultivated in the Botanic Garden at Palermo. They occur as well-marked nectariferous areas on the young branches or under-side of the leaves. In the same number, Sigr. E. Baroni describes several new species of *Lilium* from China.

THE *Bulletini* of the Italian Botanical Society for October and November contain, in addition to papers addressed especially to Italian botanists, several of more general interest. Prof. G. Cuboni describes a successful attempt to obtain in Italy the very rare germination of the seed of the double cocoa-nut of the Seychelles, *Loidoicea Sechellarum*.—Prof. P. Baccarini has found albuminoid crystalloids in the petals of a considerable number of plants belonging to the Leguminosæ, and especially in fugacious flowers; from which he draws the conclusion that they cannot, in these instances, be regarded as a reserve food-material.—Prof. A. Aloi confirms his previous statement that both terrestrial and atmospheric electricity exercise a very beneficial influence on the growth of plants, and predicts that this may be an important element in the agriculture and horticulture of the future.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 21.—"On the Calibration of the Capillary Electrometer." By George J. Burch, M.A.

In two previous papers the author has described a method of using the capillary electrometer for measuring rapid variations of E.M.F. A sensitised plate, fixed to a balanced pendulum, is carried with uniform velocity past a vertical slit, so that the movements of the meniscus are recorded in a polar curve, in which time is measured by the angular displacement, and the position of the mercury by the radius vector. In such a curve, the total indicated E.M.F. at any instant is the algebraic sum of the P.D. corresponding to the distance through which the meniscus has moved, and the P.D. corresponding to the velocity with which it is moving. In a good instrument the latter is proportional to the subnormal to the curve at that point. The validity of this method depends on the use of an apparatus of which the time-relations correspond to the formula $r = ae^{-c\theta}$, and in the present communication the author describes a practical method of determining the time-constants of a capillary. The first step is the calibration of the scale-readings. This is effected by fixing a glass millimetre scale to the focussing screen, and measuring the E.M.F.s necessary to produce a permanent excursion from the upper limit of the slit to a series of points 5, 10, 15, &c., millimetres lower. For the calibration of the subnormals two normal excursions are photographed with the capillary in the same position. In one the zero is below the field of view, and the movement is directed upwards, and in the other the zero is raised above the field of view, and the potentiometer wires reversed so as to produce a downward excursion.

The object is to obtain two curves in opposite directions running right across the plates, the exact extent and relative position of the excursions being immaterial. The subnormals to these curves are measured at points 5, 10, 15, &c., millimetres from the upper limit of the slit. The author shows that the algebraic difference between the polar subnormals to corresponding points upon two oppositely directed excursions is constant if the time-relations of the instrument agree with the formula $r = ae^{-c\theta}$. With some capillaries the velocity of the meniscus may be different, for the same acting P.D., at different parts of the tube. In such cases the multiplier which turns subnormal readings into volts is proportional to the algebraic difference of the subnormals for any given position of the meniscus. To find the absolute value of this multiplier, a third photograph is taken in which a normal excursion of known value starts from a zero-point within the field of view. The subnormal to this curve is determined for some one of the selected positions, and the corresponding acting P.D. found by subtracting the electrical value of its distance from the zero-line from the P.D. indicated by the potentiometer. The shape of this curve at its origin shows whether the instrument is dead-beat. If the velocity of the meniscus increases after the excursion has begun, the capillary should be rejected. The entire calibration can be completed in about two and a half hours, and the method is applicable to any dead-beat instrument. The author concludes with a criticism of recent papers by Prof. Einthoven on the same subject.

Physical Society, December 13.—Special General Meeting.—Prof. Reinold, Vice-President, in the chair.—The resolution, with reference to the change in the amount of the life-composition fee, passed at the special general meeting held on November 22 last, was confirmed. The ordinary meeting was then held.—Dr. John Shield read a paper on a mechanical device for performing the temperature corrections of barometers. The form of barometer to which the author has adapted his device is that devised by Dr. Colley; it is intended for general laboratory use, and is capable of being read to within 0·1 mm. The barometer tube can be moved in a vertical direction so that the lower meniscus can be adjusted to the zero of the scale. Attached to the barometer tube is a thermometer with a horizontal stem, passing in front of a scale which is fixed to the vertical scale of the barometer. The graduations of this thermometer scale, with the exception of the one passing through the 0° C. mark on the thermometer, are inclined to the vertical, and are so spaced that the reading opposite the end of the mercury column of the thermometer gives directly the correction to be applied to the observed height of the barometer (B_t) in order to obtain the reduced height (B_0). That is, the reading on the thermometer scale gives the value of $B_t(\beta - \gamma)t$ where β and γ are the coefficients of expansion of mercury and of the material of which the barometer scale is composed respectively, and t is the temperature. Mr. Boys admired the simple method the author had adopted for plotting the corrections; and said he always felt that the trouble involved in applying small corrections ought if possible to be avoided, or the correction would often be omitted. Mr. Appleyard advised the placing of the bulb of the thermometer within the barometer tube. Dr. Shield in his reply said as the barometer was only intended to read to 0·1 mm., the placing of the thermometer within the tube did not appear necessary.—A paper by Prof. Rücker, on the existence of vertical earth-air electric currents in the United Kingdom was, in the absence of the author, read by Mr. Kay. In a paper read before the British Association at Oxford, Dr. Schmidt stated that he had expanded the components of the earth's magnetic force in series, and had deduced expressions, two of which give the magnetic potential on the surface of the earth in so far as it depends on (1) internal and (2) external forces. The third series represents that part of the magnetic forces which cannot be expressed in terms of a potential, but must be due to electric currents traversing the earth's surface. Dr. Schmidt concluded that such currents amount on the average to about 0·1 ampere per square kilometre. The author has tested this conclusion, drawn from the state of the earth as a whole, by means of an examination of the line integral of the magnetic force round a re-entrant circuit, taken in the United Kingdom. The necessary data have been obtained from the results of the magnetic surveys for the epochs 1886 and 1891, carried out by the author and Dr. Thorpe. Two circuits called the α and β circuits were selected, having their greatest extension north and south, and east and west respectively. The work done by a unit magnetic pole on traversing these circuits was calculated for the epoch 1886 by means of the terrestrial lines found for that date, and also for the epoch 1891 by means (1) of the same lines when due allowance was made for secular change, and (2) of the independent set of lines found by aid of the 1891 survey. The same calculation was made for a third circuit (γ), using instead of the calculated terrestrial lines the true values of the forces and declinations as deduced from the nearest stations. The following table gives the results in amperes per square kilometre.

	α	β	γ
1886 ...	−0·026 ...	−0·004 ...	—
1891 (1) ...	+0·001 ...	−0·005 ...	—
1891 (2) ...	— ...	— ...	−0·008

From these figures the author concludes that there is not in the United Kingdom, at any rate, a vertical current amounting on the average to 0·1 ampere per square kilometre.—Mr. Watson said a few words on the difficulty experienced in determining the line integral in South Wales due to the presence of closed curves.—The Society then adjourned till January 24, 1896.

Zoological Society, December 3.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the months of October and November 1895, and called attention to the acquisition of a specimen of the wild goat of the island of Giura, in the Ægean Sea (*Capra dorcas*).—Mr. Tegetmeier exhibited a specimen of a crab with a supernumerary claw.—A communication was read from Dr. G. Stewardson Brady, F.R.S., containing a supplementary report on the Crustaceans of the group Myodocopa obtained during the *Challenger* expedition, to which were added notes on other new or imperfectly known species of this group.—Mr. F. E. Beddard, F.R.S., read papers on some points in the anatomy of *Pipa americana* and on the diaphragm and the muscular anatomy of *Xenopus*. The author added remarks on the affinities of these two anomalous Batrachians, which he considered to have been correctly placed together in the system.—Mr. W. Bateson, F.R.S., gave an acount of the colour-variations of a variable beetle of the family Chrysomelidæ (*Gonioctena variabilis*) statistically examined. It was shown that the individuals are chiefly either red spotted with black, or else greenish grey striped with black. All intermediates occurred, but were less common than the type-varieties. These facts illustrated the phenomenon of organic stability.—A communication from Mr. R. Lydekker, F.R.S., contained remarks on the affinities of the so-called extinct Giant Dormouse of Malta. The author stated that this extinct rodent did not belong

to the Myoxidæ, but rather to the Sciuridæ, unless it were necessary to assign it to a family apart. He proposed for its reception the new generic term *Leithia*.—A communication was read from Mr. W. E. Jennings Bramley, giving an account of the mode of capturing Loder's Gazelle (*Gazella loderi*), used by the Arabs of the Western Desert of Egypt.—Mr. G. A. Boulenger gave descriptions of a new snake (*Typlops nigricauda*) and of a new frog (*Chiroleptes dahlii*) from Northern Australia.—A second paper by Mr. Boulenger contained an account of the type-specimen of *Boulengerina stormsi*—an Elapoid Snake from Lake Tanganyka, recently described by M. Dollo.

Geological Society, December 4.—Dr. Henry Woodward, F.R.S., President, in the chair.—On the alteration of certain basic eruptive rocks from Brent Tor, Devon, by Frank Rutley. The author gave a detailed account of the microscopic characters of sections of rocks from Brent Tor, and discussed the history of the rocks, comparing them with Tertiary basic glass, and with the Devonian rocks of Cant Hill, which he described previously. He brought forward evidence in favour of the view that the original alteration of both the Brent Tor and Cant Hill rocks was palagonitic, and that while in the Brent Tor rocks the subsequent alteration of the palagonite into felsitic matter, magnetite, secondary felspar, epidote, and probably kaolin, and some serpentine and chlorite was complete, it was only partial in the case of the Cant Hill rocks.—The Mollusca of the Chalk Rock (part i.), by Henry Woods In the introductory part of the paper, the author gave an account of the characters, distribution, and literature of the Chalk Rock. The main part of the paper was devoted to the consideration of the cephalopoda, gasteropoda, and scaphopoda. Some new species were described, and the synonymy and distribution of the others treated in detail, figures and descriptions being given of the forms not previously well known. The account of the lamellibranchs and the general conclusions were reserved for part ii.

PARIS.

Academy of Sciences, December 9.—M. Marey in the chair.—M. Marey gave an account of his visit to the Royal Society, London, in his official capacity as President, on the occasion of the celebration of the anniversary of the foundation of that Society.—Analysis of aluminium and its alloys, by M. Henri Moissan.—Morphological study of the lymphatic capillaries of Mammifers, by M. L. Ranvier.—Valuation of meals as regards their value for baking purposes; estimation of the waste due to the husk and germ which may lower the quality of the bread, by M. Aimé Girard —On the variations of the ratio of the specific heats of fluids—carbonic acid, by M. E. H. Amagat.—On the analysis of soil by plants, by M. G. Lechartier.—Resistance of straight beams fixed on elastic supports, by M. Paul Toulon.—Application of integral invariants to the reduction to the canonic type of any system of differential equations, by M. G. Kœnigs.—On the number of classes of quadratic forms of negative determinant, by M. Matyas Lerch.—On the varieties of unicursals of three dimensions, by M. Autonne.—On orthogonal systems, by M. E. Goursat.—On the photography of stationary luminous waves, by M. Izarn.—Absorption of nitrogen by lithium in the cold, by M. H. Deslandres.—On a possible process for the separation of argon and atmospheric nitrogen, by M Claudius Limb.—Action of alcohol on mercurous iodide, by M. Maurice François. Boiling alcohol decomposes mercurous iodide. The decomposition ceases when 100 grams of liquid contain, in round numbers, 0·220 grams of mercuric iodide in solution. This action is reversible, and the inverse action stops at the same limit. The quantitative separation of mercurous and mercuric iodides by alcohol is not exact.—New synthesis of parafuchsine and its mono-, di-, tri-, and tetra-alkoyl derivatives, by M. Maurice Prud'homme.—On a mode of decomposition of some organic substances with amide or imide functions, by M. Œchsner de Coninck.—On the approximate limits of the accuracy of the estimation of marsh-gas by means of the platinum- or palladium-thread grisoumeter, by M. J. Coquillion.—On the distribution of boric acid in nature, by M. H. Jay. Boric acid is very widely spread, is absorbed by plants but rejected by the animal economy.—Solubility and activity of soluble ferments in alcoholic liquids, by M. A. Dastre.—Experiments on the "blanc de champignon" obtained by germination in a sterilised medium, by MM. J. Costantin and L. Matruchot.—On the mechanism of muscular contraction, by M. A. Imbert.—Experimental researches on the silent electric discharge, by M. Henry Bordier.—On the constitution and structure of the osseous spine of the dorsal fin in some malacopterygian fishes, by M. Léon Vaillant.—On the metamorphism of the Cambrian of the "Montagne Noire," by M. J. Bergeron.—On the measurement of the intensity of perfumes applied to biological researches, by M. Eugène Mesnard.—Fixation of tannic acid and gallic acid by silk, by M. Léo Vignon.

THE EVOLUTION OF ART.

Evolution in Art: as illustrated by the Life-histories of Designs. By Alfred C. Haddon, Professor of Zoology, Royal College of Science, Dublin. Pp. xviii + 364. (London: Walter Scott, Limited, 1895.)

THIS little book answers admirably to the idea of the Contemporary Science Series, of which it forms part, in being at once a work of original research and a popularisation of the subject. It is an example of the scientific method as applied to the history of art. That method, as cannot be too often repeated, consists essentially in patient accumulation of facts, and their classification according to their observed connections. The inferences which are drawn, after this process has been gone through, are trustworthy in direct ratio with the accuracy with which the facts have been observed and recorded and the extent of the area over which they have been collected.

The history of art is a most attractive subject; but until the last few years almost every thing written upon it had relation only to the art of very advanced communities, and for the most part only to a small department of that art. Hence little or no light was thrown upon the beginnings of human art; and only within limited provinces was any attempt made to trace its development and decay. The study of anthropology has effected a revolution in this, as in many other departments of thought. We now see that, as Prof. Haddon puts it, "in order to understand civilised art we must study barbaric art, and to elucidate this savage art must be investigated." We must, indeed, go back to the beginnings; or if we cannot literally do this, we must seek the earlier stages of art in circumstances as nearly akin as possible to those which first started it on its career. This is what Prof. Haddon has done. A biologist before he became an anthropologist, he brought to anthropological investigation a trained scientific sense. While on a zoological mission to Torres Straits he came in contact with the natives of the smaller islands, as well as of New Guinea itself, and was impressed with the exceeding interest of the anthropological data offered by tribes of savages as yet little corrupted by civilisation. Having both on the spot and, since his return, in the museums of Europe analysed and compared their artistic productions, he takes the art of this corner of the world as the point of departure for a larger inquiry. His investigations among the natives themselves enable him to speak with authority as to the meaning of their artistic motives, and to add the external witness of the people who produce the works to the internal witness of the works themselves. It was the generic differences between the art of one district in New Guinea and that of another district, which first drew his attention to the subject, and impressed upon him the truth on which he rightly insists that, in order to understand the art of any pattern, type, design, or motive whatever, its life-history must be studied; for every pattern, every type has a life-history, just as every species and every individual in the natural world has a life-history. And for this purpose every pattern and every type must be studied locally; that is to say, if the student be not actually on the spot, he must, in the first instance at least, confine his inquiries within the sphere of prevalence of the particular pattern he is studying, and not wander to different countries where similar patterns are to be found, which may spring from wholly different artistic motives.

Guided by these principles, the author begins by examining the decorative art of British New Guinea, dividing it into five regions, in which five several styles are respectively predominant. Of these, the materials at present available do not admit of a decisive opinion on the origin and motives of the art of the Fly River. The same observation applies to a great extent to the elaborate art of the Central District. In the other cases, the motives are seen to be a representation of some natural form, which becomes in course of frequent repetition degraded, until it assumes patterns where the original form is wholly unrecognisable without having the intermediate stages before the eye. The most interesting of these patterns are derivatives from the human face and from the head of the sacred frigate-bird.

Prof. Haddon then passes to a more general investigation of the material of which decorative patterns are made. He divides it into the decorative transformation and transference of artificial objects, and the decorative transformation of natural objects. In this chapter he is of course largely dependent upon the works of his predecessors; but he is able often to reinforce their conclusions from his own observations. In the following chapter he discusses the reasons which impel men to decorate objects. These he classifies into the æsthetic impulse, or desire for beauty; the desire to give information, including a summary account of the passage of picture-writing into alphabetical signs; the accumulation of wealth, by which objects originally of use, and therefore valuable, became through artistic treatment valueless for practical purposes, while they retained a more or less factitious value as symbols of wealth, and acquired at the same time an æsthetic value in consequence of the pains and skill spent upon them; and lastly, magical and religious motives. In this last section, Prof. Haddon's reputation as a student of folk-lore, or the psychological side of anthropology, gives his opinions great weight; and the conclusions of earlier inquirers, which his cautious reasoning leads him to support, must be regarded as, in the present state of our knowledge, established.

Finally, the author devotes a chapter to a full vindication of the scientific method of studying decorative art, and of his mode of procedure in the present volume. It cannot be said that the arrangement which places this chapter at the end is satisfactory. It would have been more logical to place the argument for the biological treatment of designs at the beginning; and it would, moreover, have saved some repetition, and have given a reader approaching the subject without previous scientific study of art, a preliminary grasp of the method adopted, and of the reasons for its adoption.

It is impossible here to do justice to Prof. Haddon's treatment of his subject. Although, as will be seen from

the foregoing analysis, his attention is mainly concentrated upon decorative art, the reasoning he has employed must apply to other kinds; and, indeed, he shows in the course of the volume many instances of such application. The number and interest of the questions he suggests, forbid discussion in the space at my command. The extent of ground covered necessitates dealing in a summary manner with certain portions of the field. It cannot be helped. In a work of this kind it is more important to give glimpses of results beyond those actually worked out, than it is to establish a number of conclusions in detail. Prof. Haddon is fully alive to this; and while his conclusions, as far as they go, are in the main sound, and his exposition is clear and forcible, to fulfil the more important office he voluntarily foregoes much that would have added interest in the eyes of specialists, and perhaps in the eyes of others also. For he student every page will have its own suggestions. That humbler, but much more formidable, person, the general reader, for whom the book is also intended, if he be unacquainted with the writings of Holmes, Balfour, Dr. Colley March, and Count Goblet d'Alviella, will find himself in a new world. He cannot have a more trustworthy and companionable guide, with whom to commence its exploration, than Prof. Haddon.

Most of the figures are well and clearly reproduced; but a few of them would be greatly improved by the adoption of a larger scale. Some, such as the bamboo-pipes in Fig. 1, and Buddha's footprint in Fig. 130, are almost useless, on account of their diminutive size as compared with the intricacy of their patterns.

E. SIDNEY HARTLAND.

THE FLORA OF BOURBON.

Flore de l'Ile de la Réunion [*Bourbon*] . . . *avec l'Indication des Propriétés Économiques et Industrielles des Plantes*. Par E. Jacob de Cordemoy. (Paris: 1895.)

THE appearance of Dr. Cordemoy's long-promised book on the flora of Bourbon will be welcomed with great satisfaction, as this was the only island of the Mascarene group proper of which the plants had not been worked out in detail. Dr. Cordemoy's work is not compiled on the same lines as the British Colonial Floras, and in some respects compares unfavourably with them; notably in the want of uniformity in treatment, and the absence of particulars of the general distribution of the plants. But the author has laboured under the great disadvantage of being remote from a botanical centre of literature and collections, and has done exceedingly well considering these drawbacks, except that, with his thirty-five years of experience, he might have given a much more interesting account of the vegetation, and a better summary of the facts brought to light by his investigations.

Mauritius and Bourbon, separated by about 100 miles, are nearly of the same extent; but the mountains of the latter rise to an altitude of nearly 9500 feet, or upwards of 6000 feet higher than those of Mauritius. This additional elevation adds a zone of vegetation to Bourbon which is practically unrepresented in Mauritius; yet there is no strictly Alpine element in the flora, and the presence of native species of such genera as *Ranunculus Stellaria*, and *Hypericum* hardly marks a cold climate. Perhaps the most striking thing in the flora of the two islands is the large number of characteristic genera and species common to both. For example, the indigenous palms of Bourbon are: *Hyophorbe indica*, *Dictyosperma alba*, *Acanthophœnix rubra*, *A. crinita*, and *Latania Commersonii*. These are also, all of them, indigenous in Mauritius, and nowhere also. This is a strong contrast to the strictly endemic palm-vegetation of the Seychelles. On the other hand, Bourbon possesses a bamboo, *Nastus borbonicus*, which covers extensive areas at 4250 to 6500 feet, growing to a height of 35 to 50 feet. Excluding *Pandanus utilis*, four species of screw-pine are described; all endemic, and evidently constituting a prominent feature in the landscape, both on the seashore and high up on the mountains.

Other genera and species common and restricted to the two islands are: *Cossignia pinnata* (Sapindaceæ), *Grangeria borbonica* (Rosaceæ), and *Psiloxylon mauritianum* (Lythrarieæ?).

Among characteristic genera largely developed in both islands are *Dombeya* (Malvaceæ), *Quivisia* (Meliaceæ), and the shrubby *Psiadia* (Compositæ). Among mountain shrubs of wide distribution within the African region, *Phylica nitida* and *Agauria salicifolia* are noteworthy. The former Cordemoy describes as a new species, with the remark that it may be the same as *P. mauritiana*. I have elsewhere[1] given my reasons, supported by the opinion of previous writers, for uniting the forms of *Phylica* inhabiting the Tristan da Cunha group, Amsterdam Island, Bourbon, and Mauritius under one species; and a further examination of the specimens does not alter that conviction. *Agauria salicifolia* is a common shrub on the mountains of Mauritius, Madagascar, and Continental Africa, westward to the Cameroons.

The discovery in Bourbon of *Bryodes micrantha* (Scrophularineæ) is interesting. It is a minute plant, only known at Kew from the one small specimen on which the genus was founded, collected in Mauritius by Bojer.

Hydnora africana, a root-parasite, found in some districts of South Africa, is recorded as common at Saint Paul, and as being known under the name of *Rose de Noël*. This is even more remarkable than the discovery of a new species of *Cytinus* in Madagascar.

As in Mauritius, so in Bourbon, gymnosperms are wholly wanting in the native and naturalised flora; and at present only one species each of *Podocarpus* and *Cycas* is known to inhabit Madagascar. They are both endemic. The phyllodineous *Acacia* (*A. heterophylla*), which has lately been recorded as introduced in Madagascar, and which is so near the Sandwich Islands *A. Koa*, as to be hardly distinguishable, if you did not know where your specimens came from, is said to be very common on the mountains, between about 3250 and 6500 feet. It is also common in Mauritius, and apparently undoubtedly native.

With regard to the total number of indigenous species of vascular plants, as compared with that of Mauritius, it is not easy to arrive at a satisfactory estimate, because many of the plants now commonest were probably introduced; but 1000 is, perhaps, below the actual number,

[1] "Botany of the *Challenger* Expedition," i. 2, p. 148.

as against 850 in Mauritius. The larger number may be accounted for by the greater elevation of Bourbon, as well as the divergencies in the numerical representation of the predominating natural orders. Some fourteen fewer natural orders are represented in Bourbon, but, in return, several orders are much more numerously represented.

It was known that Bourbon, as well as Mauritius, was exceedingly rich in ferns and orchids; yet few botanists will be prepared for the fact that orchids outnumber the two next highest orders combined. Orchids are absent or very rare in small remote islands, and comparatively rare in larger ones where there is a humid climate and rich vegetation; or even absent, Juan Fernandez, for example; and British India is the only large continental area, so far as I am aware, in which orchids predominate over any other order. Nearly 20 per cent. of the flowering plants of Bourbon are orchids; the total number described being 172 species, and the author expresses a doubt whether this is exhaustive. Three new genera are proposed, one, *Hemiperis*, comprising twenty-one species. Altogether seventy-two are described as new, and they are about half epiphytic and half terrestrial. Very few of these orchids are represented in the herbaria of this country, and, indeed, many of the other endemic plants of the island, especially the inconspicuous ones.

Dr. Cordemoy describes three or four new genera belonging to other orders, but mostly from somewhat imperfect materials. The most interesting is a labiate (*Mahya stellata*), supposed to be the only really indigenous member of the order, and exceedingly rare, being found only on the summit of the Grand Benard, at about 8500 feet. W. BOTTING HEMSLEY.

TECHNICAL EDUCATION.

The New Technical Educator. Vols v. and vi. (London, Paris, and Melbourne: Cassell and Co., Limited, 1895).

THESE are the concluding volumes of a valuable series of treatises on various technical subjects; the previous ones have already been noted in our columns. All the subjects are dealt with in an admirable manner, the author in each case being a specialist. The arrangement of the work is such that in most cases each volume contains information bearing upon a particular subject. A good index has been placed at the end of the last volume, and this very materially adds to the value of the work.

Prof. W. H. Greenwood's treatment of the manufacture of "Steel and Iron" is excellent. Commencing with the ores, he takes the reader through all the many processes in vogue, with ample illustrations and descriptions. The question of tests, however, appears to be generally overlooked. This is unfortunate, because it is of great importance both to the manufacturer and the engineer. In all modern specifications the quality of the material to be used is always stated, either in the form of mechanical or chemical tests.

Another well-written section is that on "the Steam Engine," by Archibald Sharp. In this case, also, the subject has been thoroughly dealt with from the beginning. The illustrations and descriptions are of recent engines, and boilers. Of the latter, the water-tube type has not been overlooked; more might have been said, however, on the subject. The locomotive is represented by one of Mr. Worsdell's compounds, and we are told that "compound locomotives are being largely used." This statement is scarcely correct, because in this country, at any rate, they are at a discount. The same author has much to say on the subject of "Gas and Oil Engines." He omits to describe the porcelain ignition tubes now largely used in place of iron.

On "Engineering Workshop Practice," by several authors, we find much general information dealing with the engineering trades. Taken as a whole, the treatment flavours more of the amateur than of the tradesman. The same cannot be said of "Electrical Engineering," by Edward A. O'Keeffe, because this subject occupies a prominent position in these volumes, having been particularly well written throughout. The last two volumes treat more particularly of the construction of incandescent lamps, accumulators and measuring instruments, concluding with descriptions of the microphone, telephone and phonograph, besides sundry details.

"Civil Engineering" has also been creditably treated from all points of view, the construction of roads naturally coming much to the front, and the praises of Telford and Macadam duly sung. An interesting account is included on the rise and progress of railways; when discussing probable speeds, we read: "The desire is now for higher speeds, and as much as 250 miles per hour is projected." This statement is far-fetched, and should have been omitted. The table giving train resistances, on p. 175, vol. v., would have been of more value had the authority been quoted. Further on, permanent way is discussed, and we are informed that "sleepers are never placed under the fish-joints." This statement is not correct. Another inaccuracy is found on page 297, where we read "that the driving-wheels of some locomotives have as much as twenty-five tons on them"; even the Great Northern people would probably plead "not guilty" to twenty tons on the driving-wheels of their famous single engines. Much useful information has been brought together under the heads of hydraulics, pumping machinery, lighthouses, ships, &c.

The "Dyeing of Textile Fabrics" is fully discussed, the author being Prof. J. J. Hummel, of the Yorkshire College; treated very much from a chemical point of view, dyers will find much to learn on this subject. In answer to the question, "What is technical education?" we find some sound remarks from the pen of Mr. Henry Cunynghame. He observes that the use of a knowledge of principles, as compared with the mere routine of the workshop, cannot be overrated; this is the distinguishing feature of the true mechanic from the factory hand. Much has been done of late years to encourage the formation of technical schools; but more must be done if we are to retain our present position as a manufacturing country. A knowledge of principles, both mechanical and chemical, is all-important; and these, in conjunction with machinery of the latest design, must surely tell in the race for trade.

The volumes before us will be of much use to those

wishing to study any of the subjects dealt with in this "Encyclopædia of Technical Education." The treatment is thorough, the illustrations numerous, and the printing good. N. J. L.

OUR BOOK SHELF.

A Laboratory Course in Experimental Physics. By W. J. Loudon, B.A., Demonstrator in Physics in the University of Toronto, and J. C. McLennan, B.A., Assistant Demonstrator in Physics in the University of Toronto. Pp. vi + 302. (New York and London: Macmillan and Co., 1895.)

THIS book, the authors tell us in the preface, is the outcome of their own experience, and is intended, in the first instance, to be used by the students at the University of Toronto, and the hope is expressed that it will be appreciated by those engaged in teaching experimental physics elsewhere.

The book is divided into two parts. Part i. is devoted to the description of elementary apparatus and elementary methods of performing simple experiments in mechanics, light, photometry, and heat. In this part students are only expected to be acquainted with the elements of algebra and trigonometry. On p. 55 is given a very neat elementary proof of the fact that the deviation of a ray of light passing through a prism is a minimum when its direction is symmetrical with respect to the refracting surfaces. We think that, considering how elementary this part is, the explanations might at times be simpler. It is not wise to indulge too frequently in such expressions as "it can be readily seen," even in matter intended for advanced students; and teachers cannot be too lucid when dealing with beginners.

Part ii. is intended for advanced students, and contains directions for experiments in acoustics, heat, electricity, and magnetism, with an appendix on the determination of gravity and on the torsion pendulum. The theory of the various experiments is given, and demands a wider mathematical knowledge, *e.g.* the laws of the transverse vibrations of strings are deduced from the equations of motion. A striking omission in this part is the little attention which is given to the corrections which have to be applied when making most accurate physical measurements.

The choice of experiments is good, the theory and descriptions of the apparatus are accurate, and the illustrations are clear. The division into elementary and advanced is not apt, as many of the experiments in Part ii. would be more suitably placed in Part i. This, however, is not a serious defect, as teachers using the book can arrange the order of the experiments to suit themselves. We certainly think that students of physics should become acquainted with the simpler electrical experiments as early as possible.

The book is well got up, and its value is greatly enhanced by the tables of physical constants at the end. We heartily recommend the work to teachers of practical physics as containing very good matter, and being accurate and free from misprints. W. G. RHODES.

The Natural History of "Eristalis tenax," or the Drone-fly. By G. B. Buckton, F.R.S. Pp. iv + 92. With illustrations. (London: Macmillan and Co., 1895.)

THE author's solid contributions to more than one branch of science may well protect him from criticism of extreme severity, but it is our duty to remark that this is not an adequate account of the drone-fly. The subject is a particularly good one. The drone-fly is very common, large for a dipterous insect, and distinguished by many interesting peculiarities of structure and habit. But the author has not realised how much work goes to the production of an exact and thorough monograph. Such a monograph demands minute investigation of the anatomy of every stage, comparison with some few allies at least, and much patient observation of the living insect. Mr. Buckton has not worked out the anatomy of the drone-fly in any stage, as the vague figures testify. Some important and very peculiar features of the larva are passed over without mention. There is no effective comparison with other insects. The habits of the larva and the fly have been attended to, and the account of the mode of life of the fly contains the only valuable facts in the book. There is much matter concerning insects in general, but this is not always either trustworthy or pertinent. Sometimes facts and theories are cited, not from the original memoirs, but from any author who happened to be at hand. Weismann on *Corethra* is quoted from Balfour, Johnston on *Culex* from Riley, Müller on mosaic vision from Mallock. The danger of this practice is illustrated by the last case, where Mr. Buckton shows that he is not fully possessed of the theory of mosaic vision. It may be useful to remark that the larvæ and egg-chains mentioned on page 19 probably belong to the very familiar *Chironomus*. The drone-fly has been studied by our author as a hobby, and he has no doubt got much pleasure out of it; but a more serious attack should be made upon it before long. L. C. M.

Working Models for Engineering Students. Engine Slide-Valves. Designed by Messrs. T. Jones, M.I.Mech.E., and T. G. Jones, B.Sc. Second edition. (Manchester: John Heywood, 1895.)

TO obtain a thorough insight into the movements of slide-valves, and to completely understand the distribution of steam, is generally a difficult matter to first-year students and engineering apprentices. These models, however, should greatly assist all who study the subject; they are neatly printed on cardboard, the important parts are sectioned and tinted, and the valves are movable so as to show their positions when the piston is at any part of the stroke. The relative positions of crank-pins and eccentrics are clearly shown, as well as the valves and steam-ports. The models are of a convenient size, being six inches long by four inches wide, and they represent eight different kinds of slide-valves. As such models must be absolutely accurate from a mechanical point of view to be of use to technical students, we must point out that No. 1 is said to represent a slide-valve common in locomotive practice; but the valve spindle is shown passing through the valve, whereas valve buckles are always used. No. 2 is a single-acting piston valve for a steam hammer. If it is considered necessary in this case to show the piston and rod, why not do it accurately? The parts shown do not represent a steam-hammer piston and part of the rod.

Model No. 5 represents a partly-balanced ordinary slide-valve. The authors omit to say that the space inside the relief ring must be open to the exhaust cavity to allow any steam leaking past the ring to escape, otherwise it would be of no good. This type of valve is now being largely used for locomotive purposes. The same defect is to be found in model No. 7.

Taken as a whole, the models are very useful for the purpose of illustration; they will be of much value to students and others interested in the subject.

Macmillan's Geography Readers. Book vii. Pp. 240. (London: Macmillan and Co., 1895).

IN this little Reader for elementary schools, instructive descriptions are given of the chief places and objects of interest to be seen in a journey through the United States; and the main historical facts concerning the New World are woven into the lessons, to give them additional brightness. The book also contains sections on ocean currents and tides, and is well illustrated; while the numerous extracts from the writings of travellers, give a good idea of the conditions and characteristics of American people.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Bury St. Edmunds Human Skull Fragment.

IN 1884 the late Mr. Henry Prigg, of Bury, exhibited before the Anthropological Institute a portion of a human skull supposed to be of Palæolithic age. The paper was printed, with an illustration from my pencil, in the *Journal* of the Anthropologica Institute, vol. xiv. p. 51. The relic was found in 1882, in the parish of Westley, in brick-earth at a depth of 7½ feet. Mr. Prigg was in the pit on the morning after the discovery, and could see no traces of a grave, or old disturbance. A few yards from the pit mentioned, a workman reported the discovery of an entire human skeleton in the brick-earth, at a depth of 8 feet, some thirty years previously.

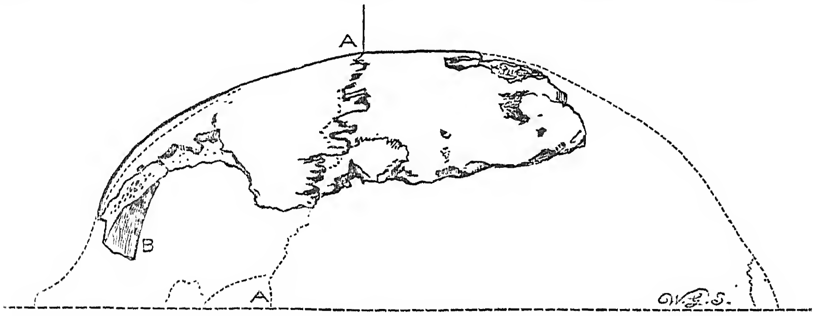

FIG. 1.—View of left side of the Bury skull fragment placed over the contou of Spy skull No. 2. Half natura size

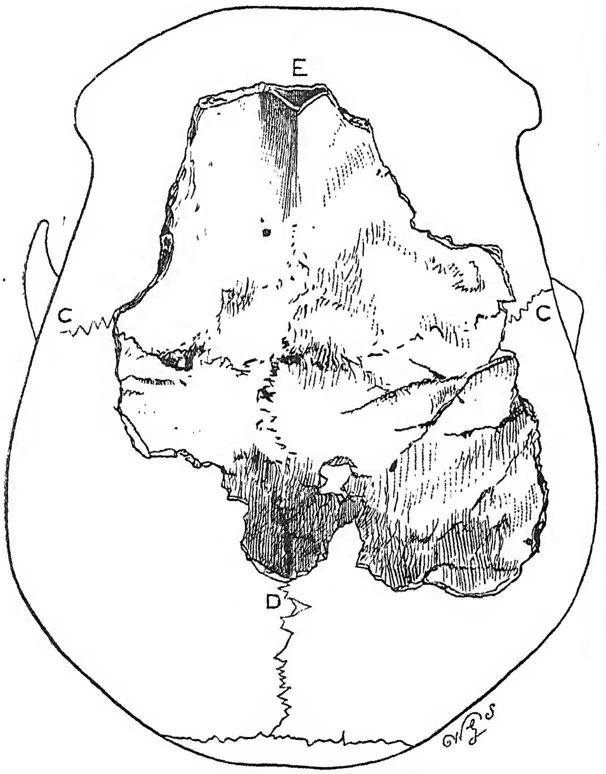

FIG. 2.—Inferior surface of Bury skull fragment placed over the sutures of Spy skull No. 2. Half natural size.

Mr. Prigg in his paper gives the briefest possible description of the skull fragment, which consists of a considerable part of a frontal bone with five inches of the coronal and a little over two inches of the sagittal sutures, and an anterior third of the left parietal bone, and a small anterior portion of the right. At the time when Mr. Prigg's paper was read, the Spy crania had not been discovered.

When the Bury fragment was in my possession in 1884, for illustration, I carefully drew not only the plate published, but the left side and inferior surface. These two illustrations have remained in my possession, and are now photographically reproduced for the first time to one-half the natural size.

The coronal suture is very clearly seen in the left side view (Fig. 1, A A). The upper A shows the point of junction of the coronal with the sagittal. This point is also well marked in the Spy skull No. 2, as well as the line of descent to the lower A. If the point of junction of the two sutures is taken as a fixed position, the close agreement of the line of descent of the sutures and the contour of the two skulls is remarkable. The Bury contour and suture is shown by solid lines, and the contour and suture of the Spy skull by dotted lines. The point B shows the inner plate of the frontal sinus, and indicates the near position of the ophyron and supraorbital prominences on the outer plate.

A comparison of the inner surface of the Bury fragment is equally confirmatory of its affinity with the Spy form. In Fig. 2, the junction of the coronal with the sagittal suture is again used as a fixed point, and the line of the coronal at C C is determined by the line of the sagittal at D. It will be seen by the illustration that the course of the coronal towards the right and left temporal bones is identical in the two examples. Part of the glabella showing the two plates of bone and air chamber is shown at E.

The mere identity of the course of the sutures is not of much importance; but the interesting point is, that when the sutures are taken as fixed guides for putting the Bury fragment in a natural position, the Spy contour results.

Dunstable. WORTHINGTON G. SMITH.

The Coronal Rays of Passion-flowers.

THE filaments, or rays, forming the corona of Passion-flowers are structures of much interest. In 1790, Sowerby described them in *Passiflora cærulea* as a "double row of horizontal, thread-like, radiated nectaries." His subsequent remarks, however, do not assure us that he regarded them as glandular, or as nectaries as we now define them. In Dr. Masters' "Contributions to the Natural History of the Passifloraceæ" (*Trans. Linn. Soc.* xvii.) no mention is made of distinct glandular structure, but Morren's opinion is quoted that "the corona is the seat of the perfume of the flower in *Passiflora quadrangularis*—a fact which he considers proved by the anatomical structure of the coronal threads, as also by the circumstance that if the processes in question be early removed the flowers remain scentless. In repeating this experiment, however," continues Dr. Masters, "I have not been able to satisfy myself of the absolute correctness of this statement. . . . Prof. Morren attributes to the conical pimple-like cells of the epidermis of the coronal filaments the formation of the odoriferous principle. These peculiar cells are found on the surface of the petals, and in the nectariferous portion of the tube of the flower. . . . We must await further evidence before we assume that in the Passion-flowers these cells really secrete the odorant principle." In Vines' "Students' Text-book," recently published, an emphatic statement is made that the coronal rays "are not glandular."

I have not yet had opportunity of studying *P. quadrangularis*, but a strongly and rather pleasantly scented hybrid, named *P. Buonapartea*, the parentage of which is stated to be *P. alata* × *P. quadrangularis*, has been under careful observation. In it the rays bear an apical tuft of glands, visible to the naked eye as a whitish knob. When magnified the glands are multicellular, relatively large, and in form remind one of those found in *Rubiaceæ*. The rays of the common *P. cærulea* are devoid of

apical glands, and the odour of the flower is rather weak, and very disagreeable. In a cross of my own raising, the parentage being *P. Buonapartea* × *P. cærulea*, the flower is delightfully odoriferous, and the rays are tipped with glands, about half as well developed as those of the former (the seed) parent. That such is the case points to the possibility of the terminal cells of the rays of such as *P. cærulea* being glandular in function in some degree. The general structure of the ray is the same in all, in respect of having conical epidermal cells, spiral vessels running up to the apex, and bearing, besides numerous conglomerate crystals, so great a number of minute starch granules as to render portions often almost black when treated with iodine.

It was repeatedly proved that the perfume of my variety was located in the rays—presumably the apices. It is singular that certain hybrids studied, stated to be between *P. alata* and *P. cærulea*, *e.g. Impératrice Eugénie*, do not bear any coronal glands, for it seems likely from analogy (flowers not yet having been observed) that *P. alata* should possess them; one being tempted to assume that species with long filaments at about right angles to the corolla will be found to bear glands, while those with shorter ones, lying at a small angle with the corolla, will not.

Yorkshire College, December 12.

Colours of Mother-o'-Pearl.

IN your issue of October 24, Mr. C. E. Benham calls attention to the fact that the colours of mother-o'-pearl cannot be due to the striations on the surface, as originally explained by Brewster. I have recently communicated a paper to the *Geological Magazine*, June 1895, in which I came to the same conclusion, and also found it impossible to accept the lamina theory as stated by Mr. Benham, for the following reasons. In certain fossilised shells, notably those of the Ammonites, the conchiolin of the shell has in course of time disappeared, and there remains not the lamina, but the prismatic structure; hence I concluded that the latter was the fundamental form in which the calcite of the shell was deposited. In *Am. Ibex*, *Elisabethæ*, &c., the shell has a chalky appearance, consisting of the detached prisms which can easily be separated by rubbing; but when the shell is carefully soaked in Canada Balsam the interspaces become filled up with the resin as they were in life, and the play of colours is perfectly reproduced. Where the original calcite has been replaced by some other mineral, such as silica or marcasite, as exemplified in the Blackdown and Gault Ammonites, it is not the lamina, but the prismatic structure that is reproduced, and in both cases the play of colours is similar to that of the original shell. In Meleagrina, whence the ordinary mother-o'-pearl is derived, the prisms of the shell are not so regular as those in the Ammonites, but the cause of the colour is the same. The laminæ of shell material, though very thin, are hardly thin enough to produce the phenomenon as Mr. Benham would have it. A full description of these prisms, and the way they affect light, is given in the paper above referred to.

ERNEST H. L. SCHWARZ.

Cape Town, November 14.

I AM indebted to you for giving me the opportunity of a remark on Mr. Schwarz's letter. Interesting and valuable though his researches were, the argument, as stated in the paper to which he refers, did not carry conviction to me. To deduce from fossils, in which secondary changes of mineralisation have admittedly taken place, conclusions as to the minute histology of recent shells, seems precarious. The connection between the prisms and the experimentally produced iridescence is not clearly proved; and the explanation of the supposed connection is based on a purely hypothetical arrangement of calcite crystals, such as mineralogists consider highly improbable. It is not proved that the iridescence experimentally produced in the fossils is the same as that occurring in a recent shell. As for Mr. Schwarz's new objection, that the laminæ are not thin enough to produce the phenomenon, this is certainly true for the calcite laminæ, and is equally fatal to Mr. Schwarz's own explanation; but some of the conchiolin laminæ are far thinner than the calcite, and might well produce interference in the light reflected from their upper and under surfaces.

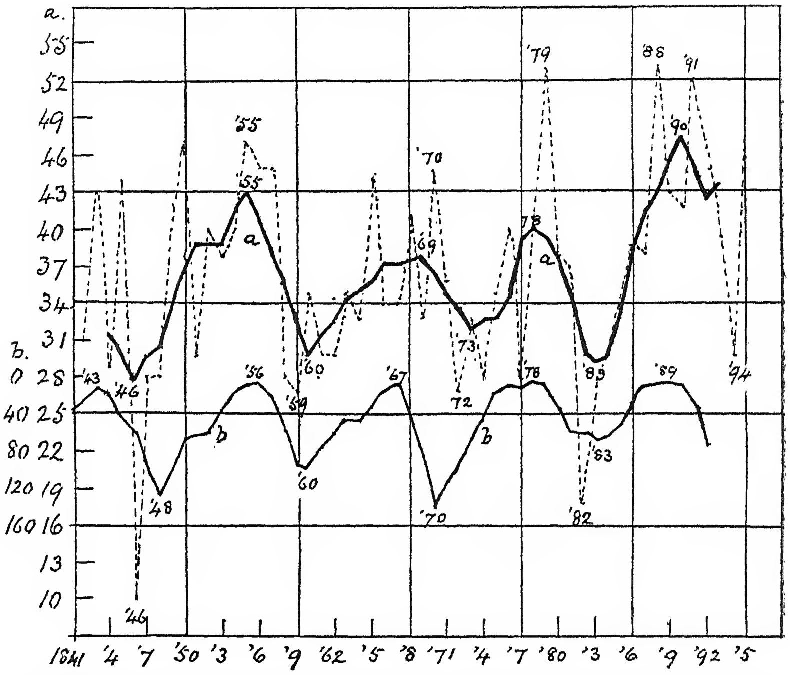
December 12.

Northerly Wind in Winter Seasons.

THE recent variations of northerly wind at Greenwich in a series of the cold seasons October to March (the winds being reduced to the four cardinal points) present some interesting features, to which I would invite attention.

These variations, since 1841, are exhibited in the dotted curve of the diagram (the ordinate figures expressing days); and a smoothing process having been applied (averages of five), we have the continuous curve (*a*). It will be observed that the four long waves brought out more clearly by this smoothed curve show a good deal of correspondence with those of the sunspot cycle, an *inverted* curve of which is given below (*b*). The higher values of northerly wind seem to be more frequent, on the whole, near sunspot minima, and the lower near maxima. Does this point to a causal relation?



(*a*) Dotted curve, variation in number of days of northerly wind, at Greenwich, in winter half (Oct., March); continuous curve, smoothed with averages of five. (Here 1855, *e.g.*, means Oct.-March 1845-5-&c.)
(*b*) Sunspot curve (inverted).

A few figures may be given. (For brevity we may designate each cold season by the year in which it *ends*; thus 1855 means October-March 1854-55).

We find sunspot minima in

	1856	1867	1878	1889

and maxima of the wind curves as follows:—

Unsmoothed curve	1855 (47)	1870 (45)	1879 (53)	1888 (53)
Smoothed curve	1855 (43·0)	1869 (37·8)	1878 (40·0)	1890 (47·4)

On the other hand we find sunspot maxima in

1848	1860	870	1883	1893

and minima of the wind curves in

Unsmoothed curve	1846 (10)	1859 (27)	1872 (27)	1882 (18)	1894 (?) (30)
Smoothed curve	1846 (27·8)	1860 (30·0)	1873 (31·8)	1883 (29·4)	

The high value for our last cold season strikes one as a little anomalous, causing an unusual break in the smoothed curve, if we suppose (as we perhaps may) that this curve has not yet reached its lowest point before rising to the next maximum (say) about 1901.

It would appear, then, that in the period considered, the northerly type of weather, in which we are generally on the eastern border of an anticyclone, has been specially prevalent about the time of minimum sunspots, giving way to some other type or types in the interval.

A careful study of the behaviour (movements of translation, of contraction and expansion, &c.) of those high and low pressure systems which determine the direction of wind, and furnish our weather generally, seems likely, in the future, to throw some useful light on the nature of solar influence on our atmosphere. In this connection, I may refer to the work of the American meteorologist, Prof. Bigelow, who finds (*Am. Journal of Science*, vol. xlviii. p. 445), that in North America, "the North Low [pressure] and the South High [pressure] belts vary in latitude directly with the solar intensity, being further north at the maximum, and further south at the minimum of the period; while the North High and the South Low belts vary inversely, that is, are further south during the maximum of sunspots."

We know that northerly wind generally means cold, and it would be interesting to trace the effects of the apparently cyclical variation in those winds, above indicated, on health and other matters.

A. B. M.

"Perlites."

Now that attention has been called in NATURE (December 12, 1895, p. 135) to two papers, by Mr. Watts and Mr. Smeeth respectively, in which perlitic structure is examined with much careful detail, may I protest at once against the use made of the word "perlite" by these authors and by the writer of the note in NATURE? So many terms ("granophyre," "picrite," "granulite," &c.) have been already strained by petrographers from their original meanings, that the fine old rock-name "perlite" may also be in danger. It was invented by Beudant in 1822 ("Voyage en Hongrie," tome i. p. 329), as a translation of the German *Perlstein*, and is the name of a glassy rock having a particular structure. It cannot be also used for the globules or cracks which characterise that structure.

GRENVILLE A. J. COLE.

Royal College of Science for Ireland, Dublin, December 13.

The Discovery of the Anti-Toxin of Snake-Poison.

No one has accused Prof. Fraser of claiming priority for his results published in June 1895 over those of Calmette published in May 1894, and over those published by the same investigator in April 1895. Such a proceeding on Prof. Fraser's part would indeed have been rash.

What I have drawn attention to is that when publishing a detailed account of experiments identical with those already published by Calmette, and when drawing conclusions from them similar to those already formulated by Calmette, he omitted to refer to Calmette's published work *in such a way* as to fairly direct attention to the fact that he (Fraser) had been completely anticipated by the French observer. I showed that this had led other persons not conversant with the progress of this branch of scientific inquiry to claim for Prof. Fraser the priority which it would certainly have been unwise for him to have claimed for himself.

I supposed that Prof. Fraser would have been glad of the opportunity of expressing regret for his omission—regret which others must feel though he apparently does not. The theory put forward by Prof. Fraser that it is not usual in communications to the Proceedings of a scientific society *extending to twenty-seven pages octavo in length*, to give more than the very briefest allusion to the latest work on the subject carried out and published by another worker and anticipating all that you have to say, is not, I think, admissible. Especially, it seems to me, is it unusual that the reference to an immediate predecessor's work should be so brief as to appear contemptuous, and so expressed as to be actually misleading (even when read by experts) in regard to the total absence of novelty in the experiments and conclusions which you are about to record as your own work.

Prof. Fraser read one paper to the Royal Society of Edinburgh on June 3, and a second on the same subject on July 15. It is impossible to imagine how many such preliminary statements Prof. Fraser would consider it right to publish, and how long a time he would allow to lapse before making the statement which one would have thought should have been preliminary to them all, viz. that the experiments have been already made, and the results published by Calmette.

London, December 22. E. RAY LANKESTER.

Male of Apus.

THE male individuals of *Apus cancriformis* are so rare, that it appears worth while recording the occurrence of one amongst the specimens used in the Zoological Laboratory in Oxford, during the ordinary course of our work. As Kozubowski showed in 1857, the only external sexual difference is the absence in the male of the egg-sac on the sixteenth appendage, known as the oostegopod of the female. This limb in the male is quite similar to its neighbours: there are no appendages modified for holding the female, such as occur in the allied form, *Branchipus*. It is generally stated that the male of *A. cancriformis* is about one-third the size of the female; whilst Lubbock found that the male of *Lepidurus productus* is larger than the female. The present male did not differ in size from the females; some of which were slightly larger, others smaller.

Oxford, December 18. W. B. BENHAM.

The Merjelen Lake.

IT may help Dr. Du Riche Preller to a precise knowledge of the condition of the Merjelen See, prior to the last *débâcle*, to inform him that on August 3 of the present year the water-level was about 60 feet below the strand-line marking the level of the col by which the lake drained into the Viesch valley. There was at that time an upper as well as a lower lake.

I have a number of photographs which show different aspects of the lake, and I do not doubt but that fairly accurate determinations of the water-level could be obtained from them.

PERCY F. KENDALL.

The Yorkshire College, Leeds, December 17.

THE PARIS ACADEMY OF SCIENCES AND THE ROYAL SOCIETY.

AT the recent anniversary meeting of the Royal Society, M. Marey, the President of the Paris Academy of Sciences, attended in his official capacity. Upon returning to France, he gave an account of his visit, and his remarks are reported in full in the *Comptes rendus* of the meeting of the Academy on December 9. The pleasant relations that exist between the Royal Society and the Paris Academy furnish standing evidence of the truth that the interests of science are international, and M. Marey's remarks on the work in connection with the Catalogue of Scientific Papers show how closely those who are devoted to the advancement of scientific knowledge are bound together. His visit is the visible sign of the kindred feeling which prevails among French and British men of science. In October last, many of our leading workers in science, art, and literature were the honoured guests of the Institute of France, and we may regard the return visit of the President of the Academy of Sciences to the Royal Society as an official expression of appreciation. It is on this account, and because the visit was a matter of unique consequence, that we print literally M. Marey's address to the Paris Academy.

"Je dois rendre compte à l'Académie, des résultats d'une mission que je viens de remplir en Angleterre. La Société Royale de Londres m'avait invité, à titre de Président en exercice de votre Compagnie, à assister aux fêtes anniversaires de sa fondation.

"C'est donc à notre Académie que s'adressait l'accueil si honorable qui m'a été fait à Londres. J'y ai entendu le Prési-

dent sortant, Lord Kelvin, et le nouveau Président, Sir J. Lister, exprimer les liens d'estime, de reconnaissance et d'amitié qui les attachent aux savants français. Dans presque tous les discours qui ont été prononcés, des paroles émues témoignaient de l'admiration que nos voisins professent pour notre regretté Pasteur.

"Je crois avoir été le fidèle interprète des sentiments qui nous animent tous en assurant les membres de la Société Royale de notre estime et de notre sympathie et en rappelant combien nous avons été touchés de l'empressement avec lequel nos Confrères et nos Correspondants anglais sont venus célébrer les fêtes du Centenaire de l'Institut de France.

"Un autre motif encore m'avait valu l'honneur d'être invité par la Société Royale. Cette savante Compagnie entreprend un travail d'une haute importance pour la Science ; il s'agit de la création d'un grand Catalogue international, rassemblant tous les travaux publiés chaque année dans le monde entier sur toutes les branches de la Science.

"La plupart de nos Confrères connaissent déjà le magnifique Ouvrage dans lequel la Société Royale a rassemblé, sous le nom de chaque auteur, les titres des travaux publiés en tous pays depuis l'année 1800 jusqu'à nos jours. Chacun peut trouver, dans ce Recueil, la série de ses propres publications : Livres, Mémoires et jusqu'aux moindres Notes y sont classés par ordre chronologique, avec indication précise du titre et de la date de leur impression. Mais un tel Recueil, excellent lorsqu'il s'agit de retrouver les travaux successifs d'un auteur, se prête mal aux recherches bibliographiques sur un sujet donné. C'est pour combler cette lacune que la Société Royale veut entreprendre l'œuvre colossale dont je viens de parler.

"Déjà beaucoup d'entre nous ont été pressentis relativement à l'opportunité d'un tel travail, et c'est sur l'avis favorable de notre Compagnie que la Société Royale a résolu de faire adresser diplomatiquement à tous les Gouvernements la demande de désigner des délégués pour une Conférence internationale, destinée à rechercher les meilleurs moyens de réaliser cette publication. Jusqu'ici, les réunions du Comité du Catalogue de la Société Royale n'ont été que préparatoires ; il semble toutefois que, sur certains points, l'accord doive être unanime. Il faut, par exemple, que le titre de chaque travail en indique aussi explicitement que possible la nature et les conclusions ; il faut que les titres de certaines Notes se répètent en différents points du répertoire, lorsqu'elles se rattachent naturellement à plusieurs sections du Catalogue. Sur tous ces points, et sur bien d'autres encore, la Commission internationale devra statuer.

"L'importance de l'entreprise ne paraît pas discutable, le nombre toujours croissant des publications scientifiques rend aujourd'hui presque impossible la connaissance des travaux effectués sur un sujet donné ; les revendications de priorité occupent, dans les Ouvrages scientifiques, une place excessive, et beaucoup de savants dépensent en pure perte des mois et des années pour avoir ignoré des travaux antérieurs sur l'objet de leurs études.

"La question est du reste à l'ordre du jour ; plusieurs Sociétés savantes ont déjà des Catalogues très complets, d'autres sont moins bien partagées, mais peuvent déjà fournir de précieux éléments pour le travail d'ensemble. L'Amérique, la Belgique, la France et plusieurs autres nations ont dernièrement réalisé de grands progrès dans la manière de cataloguer les publications scientifiques. On peut donc espérer que, si l'action diplomatique est assez prompte, les délégués des différentes nations pourront se mettre à l'œuvre dès l'année prochaine et feront concentrer pour un travail commun toutes les forces éparses aujourd'hui.

"Dans l'esprit de la Société Royale, les dernières années de ce siècle seraient consacrées à introduire, dans le classement des documents scientifiques, tous les perfectionnements que l'expérience montrera nécessaires, afin que, dès l'an 1901, l'œuvre puisse se poursuivre régulièrement dans sa forme définitive.

"Tels sont les points qui ont été discutés dans la séance du Comité à laquelle j'ai eu l'honneur d'assister et que je me suis chargé de vous transmettre officieusement, en attendant que notre Compagnie en soit saisie d'une manière officielle."

THE HABITS OF THE CUCKOO.

IN an interesting and very valuable series of papers, published in the *Journal für Ornithologie*, and the *Ornith. Monatschrift*, Dr. E. Reh records his latest observations on the parasitic habits of the common cuckoo, which seem to entirely confirm what he has already given us in his larger work, "Altes und Neues aus dem Haushalte des Kuckucks."

In 1893, not more than two kilometres from Leipzig, no less than 70 nests were found containing cuckoo eggs ; of which, 58 (83 per cent.) were in nests of the Red-backed Shrike (*Lanius collurio*).

In this year it was observed that five females were missing, while at the same time eight females were detected as new to the locality. Four new foster-parents were also noted. An approximate balance is thus preserved. Fresh arrivals are recognised by means of their eggs ; for Dr. Reh finds that the colouration of the egg of every female is peculiar to itself, and constant. Each cuckoo returns every year to the same locality, and lays its eggs only in the nests of that particular species which it, or its ancestors, happen to have adopted for that purpose. Thus, not only can every egg in a district be identified, but the number laid by any given female can be determined with a tolerable degree of accuracy.

This yearly census of the cuckoo population seems to show that the young do not return to their birthplace to breed ; or that, if they return, they do not succeed in laying eggs, being driven away by the parent birds. The evidence for this view is based partly on the fact that the numbers remain approximately fixed for each locality, and partly on the assumption that the egg of the daughter cuckoo would be similar to, but not exactly like that of the parent. It has been found, however, that the eggs which are presumably new to a locality are of types totally distinct from the types of eggs laid by birds which, so to speak, belong to the neighbourhood.

Cuckoos would seem to be more prolific than is generally supposed, an egg being deposited on alternate days from the middle of May to the middle of July. Occasionally it happens that an egg is laid every day for a short period, but such an occurrence is rare. Sometimes two eggs are found in the same nest. Such cases can always be referred to particular birds which seem to have a tendency to colonise, as is the case with an American ally, *Crotophaga*.

It is related that on one occasion a male cuckoo was seen leaving a shrike's nest, noisily calling the while, and pursued by one of the infuriated owners—whether male or female could not be determined—until at length both were lost to view. The whole proceeding produced the impression that the male had purposely provoked the chase in order to give the female time to deposit its egg. When the shrike returned it was accompanied by its mate. On the previous day this nest had been found empty ; at 3 p.m. on the afternoon on which the chase occurred it contained one shrike's egg ; on a third inspection it was observed that a cuckoo's egg had been added.

As an additional piece of evidence in support of the contention that the cuckoo first deposits its egg on the ground and thence carries it to the selected nest, Dr. Reh quotes a case in which a cuckoo's egg was found smeared with red earth similar to that which occurred in the immediate vicinity of the nest from which this egg was taken.

As is well known, cuckoos' eggs found in the nests of some species of host differ widely one from another in colouration, while those from the nests of certain other species show a great similarity amongst themselves. Dr. Reh points out further that precisely the same features obtain among the species with which these eggs are found. Thus cuckoos' eggs from nests of the red-backed shrike show a wide dissimilarity in colouration, but not more so than do those of the shrikes themselves ; but, on the other hand, cuckoos' eggs from the nests of the wren exhibit great uniformity of colouration, just as do those of the host. As an explanation of these facts, it is suggested that this variability is due to the nature of the food upon

which the young birds are reared; in the case of the shrike the diet is of a mixed nature, but is fairly uniform in the case of the wren. To secure a foundation for this theory it is assumed that cuckoos, when about to deposit their eggs, intuitively select the nests of the species by which they themselves were reared. Thus it has come about that each particular species of host rears the young of a particular race of cuckoo, the eggs of which, like those of the host, exhibit great variability when the food during the nesting period is mixed, and great uniformity when the food is uniform.

These papers are based upon a great number of observations, which are exhaustively analysed and tabulated for the benefit of those who may be fond of statistics.

THE YORKSHIRE GYPSEY-SPRINGS.

TEN miles to westward of Bridlington Quay, in Yorkshire, is the much-neglected village of Wold Newton, situated, as the name indicates, among the Wolds. It is noted as being the place where the great Yorkshire aerolite—exhibited in the British Museum—fell on December 13, 1795, but more chiefly as being the birthplace of several phenomenal springs known as gypsies (the initial letter "g" pronounced hard). The gypsies of Yorkshire resemble the nailbournes of Kent.

They are variable and intermittent springs of very clear and cold water, and appear on the surface of the chalk valleys. So freely do the calcareous wolds absorb rain, that they will allow it to pass underground as far as the blue gault on which the chalk rests. Consequently, there is scarcely a permanent surface-stream in any of the numerous hollows that lacerate the chalk-hills. The gypsies simply make their appearance in winter, or early spring, or at other periods after heavy rains, when the chalk is saturated. They will sometimes flow for two or three months, then suddenly cease, leaving scarcely a mark upon their birthplaces. They have been known to have been quite inactive for three consecutive years. The emission is often so copious as to constitute a very considerable stream, filling a drain twelve feet wide and three feet deep. This is called the gypsey-race, and it conveys the flushed tide through the villages of Burton Fleming, Rudstone, Boynton, and finally disembogues it through Bridlington harbour into the sea.

The principal gypsey-head is in a field on the left side of the road between Wold Newton and Foxholes. Another gypsey rises to the light at Kilham, seven miles away. It happened fortunate that a native of Wold Newton and I caught the springs all open last Eastertide. We trod over a deal of spongy grass-land to pursue inquiries at the gypsey-head, and were rewarded by finding water issuing through the grass where the ground was not broken, and elsewhere rushing with considerable force over the surface to the height of our boot-tops. Every one of these little eruptions contributes to the race, and by it gets eventually to the sea.

At the western extremity of the great west to east valley of the Wolds—through which ran the old Bridlington and Malton high-road—there is a spring in a bank about a furlong or two east of Wharram-le-Street. This is the fountain-head of the Wold Beck—once known locally as "Lord Carlisle's River"—which travels for some nine miles past the doors of Duggleby, Kirby Grindalythe, West and East Lutton, Helperthorpe, and Weaverthorpe (a street of valley villages). This beck gradually sinks, and finally disappears below the surface before it reaches Butterwick, its sub-surface course being lengthened or shortened as wetness or drought prevails. Some say this beck next reappears at Rudstone; but, in any case, it no doubt feeds the gypsey-head near Wold Newton when the surrounding chalk is all well saturated with rain.

The race has been known dry for three consecutive years, while once or twice it has carried two or three feet of water in mid-August. On Christmas Day, about twenty years ago, it caused the village of Burton Fleming to be flooded, and a farmer I spoke to there said he went about wet-shod for a couple of months owing to this inundation. The gypsies originally shaped a channel for themselves. An attempt to divert this at Burton Fleming proved a failure, so a broad and deep drain of the dimensions already given was cut right away to the sea, and called the gypsey-race. When in flood, it looks like a pellucid trout-stream—twelve-pound trout have been killed on its banks; but there are no fish in it now, and the bed is for miles covered with long emeraldine grass, rippling like tangles of naïads' hair along the swift current. The grass hides the chalk and every pebble; there is no babbling sound; all Yorkshire besides has no stream purer.

Only a century or two ago there were still surviving, from the days of monasteries, many silly superstitions and traditions then attached to the mysterious conduct of the gypsies. In an old tour, said to be written by Defoe, we read that "whensoever those gypsies—or, as some call them, vipsies—break out, there will certainly ensue famine or plague." In fact, as the overflowing of the Nile was to the ancients long an enigma, so was the rising of the gypsies, and may be yet so, even to some of the learned. HARWOOD BRIERLEY.

NOTES.

PROF. SYLVESTER has been elected an Associate of the Brussels Academy of Sciences.

SIR WILLIAM H. FLOWER has been elected a Foreign Member of the Royal Swedish Academy of Sciences, in the place of the late Prof. Huxley.

PROF. RAY LANKESTER has been elected a Corresponding Member of the St. Petersburg Academy of Sciences.

PROF. G. F. FITZGERALD, F.R.S., will deliver the Helmholtz Memorial Lecture at an extra meeting of the Chemical Society, to be held on January 23, 1896.

THE Valz prize of the Paris Academy of Sciences has been awarded to Mr. W. F. Denning for his observations of shooting stars, discoveries of comets, and other astronomical work.

THE Albert Lévy prize, of the value of £2000 sterling, has, says the *British Medical Journal*, been awarded by the Academy of Medicine to Drs. Behring, of Berlin, and Roux, Sub-Director of the Pasteur Institute in Paris, for their discovery of the means of curing diphtheria.

ONE of the special features of the exhibition to be held at Berlin next year is to be an interesting and instructive Department of Horticulture. This portion of the exhibition is being carried out under the direction of Herr L. Spath, an acknowledged authority on horticulture.

A CORRESPONDENT writes that on December 12, at about 6.10 p.m., he was walking towards Brownhills Station near Walsall, when he heard a loud hissing sound, and, on looking round, saw a meteor falling, of a blue colour, and dropping sparks in its course. It was travelling S. 20° W. and apparently at an angle of about 20° with the horizon.

A DESCRIPTION of another meteor has come to us through the Meteorological Office. Writing from Oakford, Bampton, North Devon, Lieut. Wolfe Murray says:—"Last night [December 17], at about 6.30 p.m., I observed a very brilliant meteor. The

brilliancy was such that it lit up the dark road (a lane with a high hedge) as though by a flash of lightning, or like a bright moonlight night. I turned and saw the meteor, almost due north from me, flash through about 5° of the sky, then separate into three distinct portions, of the following relative sizes roughly (

), and then vanish."

WE learn from the *British Medical Journal* that the Government of India have approved of a Committee, to assemble in Calcutta in January next, to revise the present cholera rules for the Forces, of which Mr. Hart spoke as inadequate and discreditable. The Committee will be composed of the Quartermaster-General in India, the Principal Medical Officers H.M. Forces in India, and the Sanitary Commissioner with the Government, associated with Mr. Hankin, the bacteriologist.

It is proposed to form a society to bring together more closely those who have taken up Reptiles as their hobby, and it is hoped that by this means interest may be kept up and mutual help secured by all concerned. Dr. Arthur Stradling has consented to become President. In order that a working basis may be secured at once, those who intend to become members should communicate with the Secretary, Rand Rectory, Wragby, Lincolnshire.

ON Friday last, several members of the British Chamber of Commerce, which has for some years advocated in the interest of English trade the adoption of the metric system in England, visited the boys' and girls' elementary schools of the Tenth Arrondissement at Paris, and listened to a lesson on the system, with the idea of seeing the ease with which it is taught and the efficiency attained. On Saturday, the members were received officially by the Paris Municipal Council, the President of which referred to the prospect that the metric system would be an additional link of fellowship between the two nations.

THE Annual Progress Report of the Geological Survey of Queensland is chiefly interesting from the account it contains of Mr. Jack's investigations into the artesian water supply of that country. A paper on the subject was read to the Australian Association nearly a year ago, so that the general results are not new. It seems probable that all the water obtained by sinking into the "Blythesdale Braystone" and other porous beds of the Lower Cretaceous is only an insignificant part of the total amount which must otherwise drain off into the sea, so that the amount of water obtained is capable of indefinite increase. There is a statistical appendix on the various artesian wells; and many matters of local geology are also dealt with in the report.

THE possibility that the ores and other vein minerals have been segregated in the veins out of the minute quantities diffused through the country-rock they traverse is so suggestive a one, that great interest attaches to any discovery that may throw light on this question. In New South Wales, auriferous granite has been known and worked for several years past in the Timbarra district. The rocks of this gold-field have recently been described by Mr. G. W. Card (*Records* Geol. Survey New South Wales, vol. iv. pt. iv. p. 154), who has found gold and silver in both the granite itself, which is a binary granite, and in eurite-veins which cut it. Moreover, small auriferous quartz-veins cut the granite. The exact mode of occurrence of the gold in the igneous rocks does not seem to have been made out.

THE diamond fields of Bingara, New South Wales, have been examined and reported on by Mr. G. A. Stonier, of the Government Geological Survey, with the view of ascertaining whether or not they resemble the deposits at Kimberley, in South Africa. It has been decided that no such resemblance can be made out, but no new light has been thrown on the genesis of the diamond. At Bingara, the diamonds are found in alluvial drifts of Tertiary age, in which pebbles of jasper, much waterworn, predominate, and nothing resembling the picrite-porphyry of Kimberley is found in the neighbourhood. It has long been held that the diamonds at Bingara were formed *in situ* in the drifts, but this view is not supported by Mr. Stonier. He suggests that the source of the diamonds is an intrusive mass of serpentine (an altered peridotite), which has metamorphosed the carboniferous rocks in the vicinity, producing great quantities of jasper, and of this, as already stated, the diamantiferous gravels are chiefly formed. The diamonds themselves are of superior quality to most of those found at Kimberley; but, being somewhat harder, take longer to polish. The largest stone found hitherto was only $2\frac{5}{8}$ carats in weight when rough, and not quite $\frac{3}{4}$ carat after it had been cut.

A RECENT number of the *Comptes rendus* (December 2, 1895, contains an account of a determination of the ratio v of the electrostatic and the electromagnetic units made by M. D. Hurmuzescu. The author has employed a method, first used by Maxwell, in which an electrostatic attraction is balanced by the repulsion between two circuits carrying a current. The electrostatic difference of potential at the ends of a known resistance R traversed by a current is obtained by an absolute electrometer with a cylindrical movable electrode. The current which passes through the resistance R also passes through an electro-dynamometer, the movable coil of which is rigidly attached to the lever carrying the attracted cylinder of the electrometer. This electro-dynamometer consists of a long solenoid with a single layer of wire, and of a small movable coil placed at the centre of this solenoid, and inclined at 90° to the axis of the solenoid. The value of the resistance R, for which the turning couples due to the electrometer and dynamometer are exactly equal, is found, and from the geometrical constants of the instrument the value of v can be calculated. The author considers that the length measurements, &c., are correct to 1 in 3000, and that the accuracy of the value of v is limited by the accuracy with which the ohm is known. The results obtained give values for v being between $3{\cdot}0005 \times 10^{10}$ and $3{\cdot}0020 \times 10^{10}$.

A NEW heavy liquid has been discovered. Mr. S. L. Penfield describes its preparation in the December number of the *American Journal of Science*. Mix equal proportions of the nitrate of silver and thallium, and on heating the mixture it fuses at 75° C., forming a clear mobile liquid of density 4·5, which mixes with water in all proportions. It can therefore be used to separate mineral particles of densities below 4·5. When still heavier particles have to be separated, the proportion of thallium may be increased. When the ratio is 3 : 4 the mixture fuses below 100° C. and has a density of about 4·7. At 2 : 4 the fusing point becomes 150° C., and the density 4·8; at 1 : 4 it is about 4·9, and fusion only takes place at 200°. Finally, when pure thallium nitrate is used, the point of fusion is 250° C., and the density closely approaches 5. This high range of densities, together with the fact that the salts do not attack many minerals, make the liquid especially valuable for mineralogical purposes. A convenient separator is described by the same author. It consists of a thimble-shaped cup into which a wide tube is made to fit. The tube can be closed at the bottom by a hollow plug. This plug being removed, the heavy liquid is poured through the tube into the thimble, and the minerals are thrown in and stirred. The heavy particles sink into the thimble, and may be removed by closing the tube with the plug, and withdrawing the thimble. The latter is then replaced, and the operation repeated with dilute liquid. With some practice an elaborate separation by densities is rapidly and easily accomplished.

A POSSIBLE method of determining the directions of atmospheric currents at high altitudes, independently of the observations of cloud movements, was suggested by Señor V. Ventosa, of the Madrid Observatory, in 1890; since then he has continued the investigation with great perseverance. The basis of the method consists in the observation of the undulations round the sun's limb, which are so trying to solar observers. In their greatest simplicity, these waves are tangential to the disc at two diametrically opposite points, and cut normally in the positions at right angles, all of them trending in the same direction. Usually, however, there are several superposed systems, and the difficulty is to separate them clearly one from another. The wind near the earth's surface is not often found to affect the appearances on the sun's limb, the explanation being that the waves produced by such a current must be greatly out of focus in the telescope. In fact, by varying the position of the eye-piece and determining the displacement necessary to bring the different systems of waves most clearly into view, the corresponding altitudes of the currents producing them can be found by applying the ordinary formula for conjugate foci. A large number of observations of this nature have been accumulated by Señor Ventosa, and as a control, observations of clouds have also been made; a tabulation of results certainly seems to indicate that the new method may be useful. Generally speaking, the direction of the superior currents is unlike that of the wind near the surface of the earth. A result of some interest is that on 150 days on which two currents were indicated, the mean height of the "neutral plane" was 2430 metres. It also appears that as the altitude increases the direction of movement usually changes in the opposite direction to the hands of a watch. The method seems to be well worth further investigation.

TWO important papers have recently been published on the effect of the electric light and of electricity on vegetation. The first is by M. Bonnier in the *Revue Générale de Botanique*. He states that a continuous electric light promotes the formation of chlorophyll, and brings about, at the same time, a simpler anatomical structure of the leaves. Under a continuous electric light the distribution of the chlorophyll in the tissues is more extended than in ordinary daylight; chlorophyll-grains make their appearance in the cortex as far as the endoderm, and even in the medullary rays and the pith. The palisade-tissue of the leaf is reduced, or entirely disappears, and the epidermal cell-walls are thinner. The bark is less developed, and the various tissues of the stem are less differentiated. When the electric light is discontinuous, as, for example, when turned on twelve hours out of the twenty-four, the effect on vegetation is intermediate between that of normal sunlight and that of a continuous electric light. Alpine plants cultivated under a continuous electric light exhibit points of structure identical with those of Arctic plants, which are exposed to almost continuous sunlight in the summer. The other paper is by Prof. A. Aloi in the *Bulletino* of the Italian Botanical Society. He adduces evidence in favour of his view that both terrestrial and atmospheric electricity exercise a favourable influence on the germination of seeds and on the growth of plants, and predicts that the employment of electricity will be a most important factor in the agriculture of the future.

WE have received a valuable memoir on the Greek earthquakes of 1894, from Dr. S. A. Papavasiliore, the director of the geodynamic section of the observatory of Athens. We have already (vol. l. p. 607) given a full account of these shocks, in summarising two preliminary papers by the same author.

THE Roman earthquake of last November 1, is the subject of a short paper read by Prof. Tacchini before the *Reale Accademia dei Lincei* ("Rendiconti," vol. iv., 1895, pp. 221–223). The area over which the shock was perceptible, without the aid of instruments, contains about 11,600 sq. km. The epicentre was probably near, or under the sea, in the neighbourhood of Ostia. Dr. Cancani estimates the depth of the seismic focus at about 15 km. Beyond the limits of the disturbed area, the shock was registered by microseismographs at Ischia, Siena and Florence. The times recorded by Prof. Tacchini, for Rome and Siena, give a velocity of almost exactly 2 km. per second.

IN the last number of the *Ornithologische Monatsberichte* (1895, p. 196) will be found an announcement that the German Zoological Society of Berlin has in contemplation a very important work, which will be entitled "Das Tierreich. Eine Zusammenstellung und Kennzeichnung der rezenten Tierformen." The somewhat ambitious aim of this publication is, if we understand rightly, to give on an uniform plan descriptions of all the known species of the animal kingdom, together with their distribution and most important synonymy. Prof. F. E. Schultze, of Berlin, has undertaken the general editorship of this work, but will be assisted by specialists in the different branches of zoology.

THE Royal Meteorological Institute of the Netherlands has made a valuable contribution to maritime meteorology by the publication of a large folio atlas of the Guinea and equatorial currents, embracing that part of the Atlantic Ocean between lat. 2° and 24° N., and from the west coast of Africa to long. 29° W., which includes the limits of the African North Polar current. The charts, of which there are several for each month, show clearly how the Guinea current divides into two branches, one setting to N.E. and the other to S.E., the various changes in the temperature of air and sea-surface, the regions of trade winds, calms, rain and other phenomena. The principal direction of the Guinea current being towards the east, while the equatorial currents set towards the west, the former is represented in black and the latter in red. The materials for the charts have been obtained entirely from logs kept on Dutch vessels.

AN interesting paper by Miss Grace E. Cooley is reprinted from the *Memoirs* of the Boston Society of Natural History, on the reserve-cellulose of the seeds of *Liliaceæ* and of some related orders. She states that reserve-cellulose appears, as such, on the walls of the cells soon after the endosperm is formed. Sugar and oil are present in the cells before the appearance of reserve-cellulose and during the process of the thickening of the wall, the sugar being formed first. The reserve-cellulose appears first at the angles of the cells, and extends thence to the walls. The cells of the endosperm near the chalaza are the first to have their walls thickened; those next the integuments are next affected, and the cells near the embryo are the last to mature. The paper is illustrated by six quarto plates.

A VALUABLE monograph on water supplies, by Mr. Allen Hazen has just been published, and should prove of great value to engineers and others in charge of water-works. Mr. Hazen was lately chemist in charge of the well-known Lawrence experiment station of the Massachusetts State Board of Health, and is, therefore, specially qualified for the task he has undertaken, and in the carrying out of which he has been so successful. No trouble has been spared to obtain the latest and most trustworthy information on water-works from all parts of the world. The change which has come over the conduct of water-works since the introduction of the modern methods of bacteriology is, of course, shown very clearly, and it is pointed out how, in our country, Dr. Percy Frankland's investigations, published in 1885, on the removal of bacteria by means of sand-filtration at the London Water-works, and in Germany those of Wolffhügel, Plagge and Proskauer at the Berlin Water-works, published in 1886 and 1887, were the means of furnishing the first insight into the hygienic significance of filtration.

WE have on our table several volumes published by learned societies, but limits of space will not permit us to do more than refer to them briefly. One of these volumes is the twenty-second (new series) of the *Proceedings* of the American Association of Arts and Sciences, and contains twenty-two papers read before the Association between April 1894 and May 1895; among them being papers on the North American Centhophili, by Mr. S. H. Scudder; nitro-paraffine salts, and bivalent carbon, by J. U. Nef; wave-lengths of electricity on iron wires, by Mr. C. E. St. John; the blastodermic vesicle of *Sus scrofa domesticus*, by Mr. A. W. Weysse; ternary mixtures, by Mr. W. D. Bancroft; a revision of the atomic weight of strontium, by Mr. T. W. Richards; and on the relation of hysteresis to temperature, by Messrs. F. A. Laws and H. E. Warren. Another volume to which we can only briefly refer is the *Atti d. Accademia d. Scienze Fisiche e Matematiche* of Naples (vol. ii second series). In this we find memoirs on Italian Hymenoptera, by Prof. A. Costa; on certain Abelian equations, by Prof. V. Thollame; comparison of Right Ascensions simultaneously determined at Capodimonte and Cordoba, by Prof. A. Nobile; earth-currents, by Prof. Palmieri; Italian fossil ichthyology, by Prof. F. Bassani; and several others. We have also received a volume of the *Journal of Conchology*, the first published under the direction of the Conchological Society; vol. xxvi. of the *Proceedings* of the Boston Society of Natural History (part iv. 1894–95); and a number of maps from the Geological Survey of Canada. One batch of these maps exhibits the principal auriferous creeks in the Cariboo mining district, British Columbia; a second bundle refers to the geology of Guysborough, Antigonish, and Pictou Counties, Nova Scotia; while a third contains a geological and topographical map of the southern part of the lake of the Woods and Rainy River, Ontario, Eastern Townships Map, Quebec, and a sheet showing the geological character of South-west Nova Scotia. Finally, we have to acknowledge the receipt of vol. v. part i. (second series) of the *Proceedings* of the California Academy of Sciences, a volume of nearly eight hundred pages filled with valuable papers on Californian natural history; and the second volume of "Beiträge zur Geophysik," edited by Prof. Dr. G. Gerland. In this volume we find a speculative paper on terrestrial magnetism, by Prof. A. Schmidt; a very long account and discussion of observations made with the horizontal pendulum at Strassburg, during 1892–94, by the late Dr. E. von Rebeur-Paschwitz; an extensive collection of observations of submarine earthquakes and eruptions, by Dr. E. Rudolph; and a critical study of the mean level of the solid crust of the earth, of the land and water areas, and of the relation between the land above sea-level and oceanic depressions, by Dr. H. Wagner.

OUR ASTRONOMICAL COLUMN.

ORBITS AND ORIGIN OF COMETS.—The investigations of Schiaparelli led to the conclusion that comets moving in parabolic orbits must have originally had a very small velocity with respect to the sun, and that, apart from planetary perturbations, the probability of elliptic orbits is very small. The latter fact is demonstrated in a somewhat different way by M. V. Wellmann (*Bulletin Astronomique*, vol. xii. p. 515), the absolute velocities of the sun and comets being introduced. This method leads to the conclusion that the formation of hyperbolas is much more probable than that of ellipses, and that ellipses of large dimensions are much less probable than smaller ones; further, the supposed parabolic orbits which have been calculated are probably nearly all hyberbolas.

In conformity with the nebular hypothesis, M. Wellmann regards the substance of which comets are formed as the débris of nebulous matter not attached to any system in the process of condensation, but in unstable equilibrium, and having nearly the same proper movement as neighbouring centres of condensation. Eventually assuming a hyperbolic orbit round a neighbouring sun, the "cosmic cloud" passes off into space, and may become attached to our system *en route*.

M. Wellmann goes on to demonstrate that under the influence of a solar electrical repulsion, elliptic orbits will approach the parabolic form. Hence, in calculating the definitive orbits of comets, this repulsion should not be lost sight of; even neglecting planetary perturbations, a comet may not move rigorously in a conic section. In cases where calculation and observations are discordant, it is suggested that a reconciliation be attempted by supposing that the "constant of attraction" is itself variable, in consequence of the varying electrical repulsion. M. Wellmann also seems to be of opinion that this force of repulsion may be found sufficient to explain the inequalities in the movement of Mercury, which Leverrier ascribed to a possible intra-mercurial planet; the suggestion that the law of gravitation is not strictly true (NATURE, vol. li. p. 183), adds to the probability of this explanation.

COMET BROOKS, 1895.—Attention is drawn by Dr. Deichmüller to a striking similarity between the elements of Comet Brooks 1895 and those of the comet of 1652 (*Ast. Nach.*, 3322); this is shown by the following comparison, in which Kreutz's elements for Comet Brooks are adopted:—

Comet 1652.	Comet Brooks.
T = 1652 Nov. 13	T = 1895 Oct. 21
$\omega = 300^\circ\ 10'\cdot6$ } 1895	$\omega = 298^\circ\ 13'\cdot0$ } 1895
$\Omega = 91\ 33\cdot0$	$\Omega = 83\ 9\cdot2$
$i = 79\ 27\cdot7$	$i = 75\ 22\cdot8$
$q = 0\cdot847$	$q = 0\cdot839$

The continued ephemeris for the comet, following Dr. Berberich, is as follows:—

	R.A. h. m. s.	Decl. ° ′
Dec. 27	3 18 39	+68 45·1
28	3 9 42	68 34·2
29	3 1 38	68 22·1
30	2 54 22	68 9·2
31	2 47 51	+67 55·6

THE MOVEMENTS OF HORIZONTAL PENDULUMS.

THE movements of horizontal pendulums referred to in this note are those which have been observed in Japan and the Isle of Wight. In reports to the British Association on the earthquake and volcanic phenomena of Japan in the years 1883, 1884, 1885, 1887, 1888, 1892, 1893, and 1894, abstracts are given of work which has been carried out in that country in the investigation of earth tremors or pulsations, diurnal waves, and other earth movements. The Report for 1892 describes a pair of extremely light horizontal pendulums, the movements of which, with the aid of mirrors and lenses, were recorded on photographic plates and films, and gives some account of the analysis of the resulting records. The observations were continued during the following year, when it was observed that the direction of earthquake movement in many cases coincided with the direction in which strata had been folded to form mountain ranges bordering the Tokio plain. Another observation was that certain earthquakes had been preceded by an abnormal amount of tilting. During the last year, largely in consequence of the liberality of the Royal Society of London, I have been able to extend these observations, and records have been obtained from horizontal pendulums, each provided with photographic recording apparatus, from nineteen installations. The more important of these installations were as follows. At Tokio in my house, on a massive stone column. At a place 1000 feet distant, in an underground chamber, excavated in the alluvium on a concrete bed. At Kanagawa the observatory was in an artificial cave, driven at a depth of about 50 feet in soft tuff rock beneath its junction with overlying alluvium. At Yokohama two instruments were placed in a cave on the tuff rock, about two feet below its junction with the alluvium. At Kamakura two instruments were placed in a cave on hard tuff, which dips at an angle of 30° north-east.

These instruments were oriented so that their booms pointed north-west or north-east, or parallel and at right angles to the dip of the rocks. The localities mentioned are at distances from Tokio of twenty, twenty-three, and about thirty-three miles.

The remaining installations were on brick columns rising from a bed of concrete on the alluvium, the localities being chosen with regard to the surface configuration and the proximity or absence of a covering of forest or buildings which would influence the effects of solar radiation. Underground and in the caves, which represent seven out of the nineteen installations, the daily change in temperature was not appreciable on the diagram from a self-recording thermometer. At other stations this change was often very great.

The Instruments.

The pendulums consisted of a horizontal boom about 5 feet in length, held up by a fine brass wire. They had different degrees of sensitiveness. Usually the adjustment was such that the outer end of the boom was displaced 1 mm. by tilting the bed plate of the apparatus from 0″·1 to 0″·5. At the extremity of the boom there is a light metal plate with a slit in it parallel to the length of the boom. Underneath this floating slit, but at right angles to it, there is a narrow slit in the top of a box. Light, after passing through the two slits, goes into the box as a point which is received on a drum carrying a photographic film, which usually lasted one week.

No accuracy of adjustment is required, and if the pendulum is steady without the aid of a single lens, the photographic trace is a remarkably clear line.

If there are two slits—one broad and the other narrow—in the floating plate, two lines may be produced, one of which is thick, and the other extremely fine. For quick movements of the pendulum, the best diagram is given by the former, whilst for slow displacements the latter has the clearer definition.

A modification of these arrangements is one which I used in Japan, and which is now in operation at Shide, in the Isle of Wight. In this instrument the boom is built up of straw and reed about 2·5 feet long, and weighs less than ·25 oz. At its outer end there is a small mica plate, which is blackened, and has two slits in it parallel to the length of the boom. At a distance of 1·5 inches from its inner end, where there is a brass socket and an agate cup, a pivoted weight is so arranged that it balances the outer part of the boom. The apparatus is therefore equivalent to an extremely light conical pendulum seismograph, which multiplies tremor-like motion about sixteen times, but which is at the same time very sensitive to changes in the vertical. When the pendulum has a period of sixteen or eighteen seconds, one millimetre deflection of the end of the boom indicates a tilting of 0″·70. The record is received upon a roll of bromide paper passing beneath a fixed slit in the lid of a box, above which is the boom and mica plate. This moves at a rate of about forty-two millimetres per hour. Should this paper move at a varying speed, this is checked by an ordinary watch so placed upon the lid of the box with the fixed slit, that its long hand every hour crosses freely over a portion of this slit not covered by the floating plate, and by eclipsing the light, causes hourly time-marks to be made on the band of bromide. On many occasions I have caused the pendulum to move at *known* times, and subsequently determined the times at which these disturbances took place by measurements made on the bromide film after development. The errors usually varied between three and ten seconds.

These pendulums have worked well in damp caves and with unskilled assistants. One assistant was a shopkeeper's daughter, twelve years old, whose duty it was to refill and light a benzine lamp every twenty-four hours. The records obtained were very much freer from tremor effects than anything I have obtained when working with a pendulum, the boom of which was a two-inch piece of aluminium wire held in position by a quartz fibre, and giving its record by mirrors and lenses.

The movements recorded have been as follows.

(1) *The Wandering and Long-period Movements of Pendulums.*

All the horizontal pendulums wherever situated have slowly wandered from their normal position. Those on the rock have often gradually moved to one side and then returned, the double excursion usually taking from two days to a week. Underground on alluvium *within twelve feet of water-level* the wandering was at times so great that the spot of light left the film, which was two inches broad, and readjustments were often necessary. From the readings of the end of the pointers, it would appear that in some cases at least, had the pendulums been given sufficient time they might have returned to their starting point. The pendulum in my house, one thousand feet distant from those underground, but *thirty-six feet above water-level*, although usually more sensitive than those beneath the surface, wandered to a less degree. These wanderings might be due to a local warping of the supporting column, but inasmuch as it has generally happened that the periods of great movement and of comparative rest of different instruments have coincided in time, it would seem that the movements are in all probability due to a more general cause. Because great movements have usually been marked (but by no means always) at or after a rainfall, some of them may be attributed to fluctuations in the volume and flow of underground water, the pendulum nearest to this water moving the most.

The other movements, especially those of the pendulum, situated in my house, and those of the instruments on the rock, have been accompanied by local earthquakes, conveying the impression that they represent actual rock bending, the earthquakes being interruptions in the process. As the number of observations are limited, and as I am not in a position to determine which of the earthquakes recorded in Tokio are of local origin, and which originated at a distance, although the materials for making this determination have been accumulated at the Central Observatory in Tokio, the matter is one requiring further attention.

Two pendulums on the alluvium, four hundred yards distant from each other and very differently installed, for periods varying between four and forty days, have moved at the same time in the same directions.

These movements may therefore be due to some general cause. A rough agreement with a barometric curve suggests the idea that the cause is due to variations in atmospheric pressure, but it is equally possible that they may be due to a greater evaporation or precipitation of moisture on one side of these stations than upon the other sides.

(2) *Diurnal Waves.*

By a diurnal wave I mean a deviation of the vertical during one portion of a given period of twenty-four hours in one direction, followed by a retrograde motion during the remaining portion of this interval. On rock foundations my instruments, which never had a sensibility exceeding 1 mm. deflection for a tilt of 0″·1, have failed to show such a movement. With instruments having a greater sensibility it is likely that its presence would be detected. These movements, which may, for example, be shown by a westerly displacement of a pendulum through a distance of from 2 to 40 mm. from about 6 a.m. until about 3 p.m., and an easterly motion until the following morning, may be best studied from diagrams on films which have moved at a rate of about 3 or 4 inches per day.

In the underground chamber in the alluvium, within 12 feet of the surface, where the daily change in temperature was less than 1° C., the daily waves were often marked. On the surface at my house, on a good foundation protected by a long building, the wave was marked, but slight.

At stations protected on all sides by high trees from the sun it was feeble. At all other stations, where on one side at least there was open ground exposed to the sun, with the *exception of rainy or cloudy days, when the photographic trace was a straight line, it was very marked, the deflection sometimes amounting to 40 millimetres*. On one hill, from about 6 a.m. to 6 p.m. the motion was westwards, while at the other side of a swampy valley running N.N.W. the movements were at the same hour almost in a contrary direction. It would appear that on every fine day the trees on the hills on the two sides of this valley bow first towards and then away from each other.

For the present I am inclined to regard these phenomena as being due to a tilting of the surface in consequence of the evaporation of moisture. This effect extends to some depth.

On open ground in the morning more moisture is taken away from the eastern side of a station, than from the western side, and therefore the eastern side, being relieved of a load, rises, and the pendulum swings westwards.

In the afternoon this action is reversed, and the pendulum turns eastwards.

The waves due to this effect differ in time of occurrence and in amplitude according to the character of the locality in which they are observed.

The movement at night is slight. It may be a continuation of the sun effect modified by the precipitation of dew from the atmosphere, and by the condensation of aqueous vapour rising in ground heated during the day but chilled on its surface after sunset. The sub-surface condensation sometimes represents a load one-tenth of that taken away by evaporation. Like dew

and evaporation, its amount varies daily, and with localit and on two sides of a given station it reaches a maximum at different times.

Experiments bearing upon these Suggestions.

(1) Ten men and boys, representing a load of about 1000 lbs., at a distance of 15 feet from the stone column carrying the pendulum in my house, causes it to move as if the ground had been depressed upon the side of the load.

(2) By quickly emptying a well, which is distant about 100 feet from the above column, of about two tons of water, which was run off down a hill, the pendulum moved away from the well, behaving as if the ground had been relieved of a load on that side.

(3) A self-recording tide-gauge was set up in an unused well 80 yards distant from the underground chamber. This showed that the water in the well rose and fell $\frac{1}{4}$ to $\frac{1}{2}$ inch *twice* every 24 hours. The times of sinking, which occur in the morning and the evening, may correspond with the times at which the most water is being drawn from wells in the city. I have not determined whether these movements have any influence upon a small wave which is often superimposed upon the large diurnal wave.

(4) I find from experiment that on fine days the ground in my garden may lose by evaporation 4 or 5 lbs. of moisture per square yard, or from an area measuring 20 by 20 yards about 1 ton.

I also observe that during a bright fine day that, in most cases, pendulums move away from areas that are being relieved of loads in this manner, and which may therefore be rising.

(5) Because it often happens that a board which has been lying on the grass all night is found in the morning to be wet on its under side, whilst all around the grass may be dry, the following experiment was made on sub-surface condensation. Two shallow trays about 1 foot 6 inches square were filled with earth, and placed on a flat surface of earth in my garden. One of these trays had a bottom of sheet tin, whilst the other had a bottom of fine wire netting. These were weighed morning and evening, and it was found that sometimes the box with the fine wire netting had increased in weight, while the other had not changed. The inference from this is, that during a hot day the ground is sensibly heated to a depth of one foot. This was proved by diagrams from self-recording thermometers, which for periods of a week had been buried at varying depths. After sunset the surface of the ground is quickly chilled, and aqueous vapour rising into this is condensed to augment the surface weight.

An open area, which during a day may have lost more weight by evaporation than a neighbouring area which is covered, will, if both areas are connected with the same subterranean water supply, gain the most in weight, not only by an action of this sort, but also by the condensation of moisture as it escapes from the surface, and by the precipitation of moisture from the atmosphere. These actions may in part account for the retrograde motion of pendulums during the night. Although differential evaporations and condensations are apparently sufficient to account for certain observations made in Japan, other observations exist to which they are not so apparently applicable. The cause of diurnal waves is therefore not yet known with certainty.

(3) *Earth Tremors.*

The continuous photographic records taken in Japan have thrown much new light upon the occurrence of tremors, while an experiment made at Shide in the Isle of Wight, where a light horizontal pendulum has been established to record earthquakes having their origins in distant localities, has indicated a cause of movements which probably have often been attributed to movements of the ground.

We know that tremors are more frequent during the winter than during the summer, that they are frequent with a low barometer, and still more frequent when the locality of observation is crossed by a steep barometrical gradient. From these latter accompanying conditions, it may be inferred that tremors may occur whenever a strong wind is blowing, although near to the observing station the atmosphere may be perfectly calm. Recent observations in Japan have shown that tremors are more frequent during the night than they are during the day, and that maxima of motion are reached between 5 and 9 a.m. In fact, some instruments have always shown movements about these hours. One very important observation is that the greatest movements have been recorded by the lightest pendulums. For example, a pendulum having a boom from one quarter to four inches in length is a better tremor recorder than one which has a boom several feet in length.

The pendulum at Shide was set up upon a newly-built brick pier. Because moisture was given off from this, the inside of the covering case became exceedingly damp, and the bromide film became sticky. To overcome this difficulty, two trays of calcium chloride were placed inside the covering. A few minutes after this it was observed that the pendulum commenced to swing. When the calcium chloride was removed the pendulum came to rest. This experiment was repeated several times, and the conclusion arrived at was that rapid desiccation produced air currents of sufficient intensity to cause a light pendulum to move, and the diagrams of these movements are not distinguishable from those attributed to *earth* tremors. Although experiment has shown that differences in temperature of the walls enclosing a light pendulum will cause the same to swing, I have no reason to think that movements due to such causes have been recorded. All that can be said at present is that a difference in the rate at which moisture is absorbed by or evaporated from the different walls of a casing covering a light pendulum, may cause the same to swing. Before we should attempt to explain why such movements are marked at particular hours, and occur with certain meteorological conditions, the necessity of further experiments is obvious. Air currents can hardly explain a set of tremors lasting several hours, where a seventeen seconds pendulum moves back and forth with uniform amplitude and a uniform period of two or three minutes.

(4) *Earthquakes.*

At Kamakura, on the hard rock, the greatest earthquake motion has been given by the pendulum which records tilting parallel to the dip—suggesting the idea that in this direction there is an easier yielding (like the opening and shutting of a concertina) than there is in a direction parallel to the strike. The movements, even for unfelt earthquakes, are sometimes as much as 40 mm., and a disturbance may continue for several hours. On March 22, I and my colleague, Mr. C. D. West, watched an earthquake for 1 hour and 47 minutes, during which time the pendulum did not *swing*, but was *forced* backwards and forwards intermittently, and with extreme irregularity. These earthquakes are in the form of earth waves, and usually come from a great distance. A sharp shock which may be felt throughout Tokio and at many places in the country, does not disturb the pendulums, and it is difficult to find a blurr on the photographic trace.

As in previous years, before certain local earthquakes I have observed abnormal tilting, an explanation for which is suggested in the section on the wandering of pendulums. It is seldom that abnormal tilting has taken place without local disturbances. Local disturbances, unless they are large, which fortunately is of rare occurrence, are only recorded by seismographs.

One disturbance which I recorded at three stations in Japan was one which had its origin near to the antipodes of that country in the Argentine Republic. The conclusion to be derived from this and other observations is that a large earthquake may be recorded at any point upon the surface of the earth. The preliminary tremors seem to reach distant places with a velocity twice or three times that with which mechanical vibrations can be transmitted through glass or steel. Possibly they come *through* our earth, which therefore may have a higher effective rigidity than hitherto supposed. The undulatory motions which follow the tremors may be transmitted as surface quasi-elastic gravitational waves. Their velocity of propagation lies within the limits of expectation. The chief object of the instrument established in the Isle of Wight is to determine whether it is sufficient to record the unfelt movements due to earthquakes originating in distant localities.

The first certain records of earthquakes having their origin at great distances were obtained by Dr. E. von Rebeur-Paschwitz, whose recent death has deprived the world of one of the most active workers in the new field which has been opened to seismologists.

JOHN MILNE.

THE ANTWERP METEOROLOGICAL CONGRESS.

TAKING advantage of the attendance of numerous visitors, scientific and otherwise, that the Antwerp Exhibition was likely to attract, it was proposed to hold, under the auspices of the Geographical Society of that city, a congress on meteor-

ology, aerial navigation, and allied subjects, with the particular object—as we gather from the circular convening the congress—of promoting the methodical and general observation of aerial currents. Authorities propose, but contributors decide, the result and character of the meeting, and the *compte rendu* of the congress, which has just reached us, shows that while a variety of interesting topics was brought under the notice of the members present, and discussed with greater or less detail, the ultimate aim of the promoters does not seem to have been materially advanced. Of course, the awakening of public opinion and the diffusion of information are always desirable, and the Committee responsible for the congress are to be congratulated upon the general success which has attended their efforts, though it may not be precisely in the direction they proposed to themselves.

One circumstance certainly told against the development of any complete plan, demanding the co-operation of many nationalities. The date of the congress (August 16–18) was unfortunately chosen. It clashed with the meeting of professional meteorologists, who were in session at Upsala, and thus prevented the attendance of those who could have given authority to any well-considered scheme, whose guidance would have been welcome, and whose reputation would have added weight. The President (Lieut.-General Wauwermans) had to announce, therefore, many letters of apology for non-attendance from men of science who had hoped to be present. His address was in the main historical, dealing with the progress of aeronautics and ballooning from the time of Montgolfier to the present, and a consideration of the benefits that would accrue to many mechanical applications from the more perfect knowledge of atmospheric motion and aerial currents. This address was delivered to the whole congress, which afterwards divided into two Sections—one, under the presidency of M. Lancaster, to discuss the subject of aerial currents; the other, directed by M. Van den Borren, more immediately concerning itself with aerodynamics.

To the first Section, M. Lagrange contributed a paper on the sympathetic movements of freely-suspended needles, whether magnetised or not. These practical experiments are the outcome or completion of a mathematical inquiry, published by the author in 1892, entitled, "Étude sur le Système des Forces du Monde physique." The experimental inquiry has been spread over more than two years; while two sets of apparatus—one in the cellar of the observatory, the other on a level with the ground—have been under observation. The direction in which the needles point is not constant; but both sets show a tendency to travel in azimuth from north-west to south-east from April to June, and then to retrograde towards the original position. The reason for this oscillation is discussed at great length; the author attributes it to the mechanical conditions under which a permeating fluid similar to ether would be placed when affected by all the forces, gravitational and electrical, that are continually operative. The practical result is, that further observations, conducted at a depth 30 metres below the surface, are to be prosecuted at the Royal Observatory, Brussels, and a member of the congress will carry out similar observations at the Meteorological Institute of Roumania. Canon Spée discussed the well-worn question of a possible connection between the area of spotted surface on the sun and the temperature of the earth, and, like others before him, is driven to the conclusion that any connection is not apparent. The meeting closed with a new theory of tides, both oceanic and atmospheric, but the "new" theory was not well received, and is not described in the *Compte rendu*.

At he second meeting of the Section, some papers of minor importance were read and discussed. One member read a note on the treatment of diseases of the ear by compressed air, and invoked the aid of meteorologists in a matter of aero-therapeutics. Another had something to say on the forces that affect the rotation of the earth, but this was summarily dismissed as a theory "qui aboutit à la fois à des déductions d'ordre scientifique et d'ordre philosophique." Another had arranged a system of magnetic needles with a view to the solution of the problem of weather prediction. The subjects, it will be seen, were sufficiently varied; we can only refer to two. One, by M. Lancaster, on the preparation of synoptic charts, in which he insisted on the regular publication of maps showing atmospheric currents. He indicated the progress that had been made in investigations of that character, and suggested the formation of an international bureau for the consideration of the subject. A vote of the congress supporting his views was forwarded to the Meteorological Congress sitting at Upsala.

M. Plumandon, meteorologist to the Observatory of the Puy de Dome, read a paper on the causes of storms and atmospheric disturbances. He had availed himself of the difference of altitude of the Puy de Dome (1467 m.) and of Clermont Ferrand (388 m.) to compare the variations of barometric pressure at the two levels. In summer the pressure is raised less above or falls more below the mean value at Clermont than at the summit of the Puy de Dome. The opposite rule obtains in the winter. M. Plumandon deduces from his discussion that the production of storms coincides with the greatest separation of the two barometric curves, and that storms cease when the separation is sufficiently small. Put otherwise, this means that storms occur when the ascending currents reach a sufficient intensity, and, further, that absolute values of the pressure are of less importance in producing storms than the magnitude of the separation of the barometric curves at a high and low level. M. Plumandon has also interesting remarks on the relative velocities of wind at high and low stations in the same district, derived from observations at Pic du Midi and Toulouse, at Tour Eiffel and Parc Saint Maur, Paris, and other places, from which it appears that the higher station does not always suffer most from violent winds, but that there are regions at considerable altitude where the air is on the whole less agitated than at the surface of the ground.

In the Section devoted to aerodynamics, M. Van den Borren gave an able address on the subject of aerial navigation as it stands to-day, enriched by the experiments of many able mechanicians. M. Borren, as chief of the military aerostatic service of Belgium, and having charge of the School of Aerostation at Antwerp, was able to give an interesting account of what had been there accomplished under his own eye. Experiments have been carried on to determine the resistance offered by the air to planes at different inclinations, and to surfaces of various figure, as well as to the preparation of machinery arranged for different rates of locomotion and constructed of various materials with the view of determining the friction of the air on different substances. That is to say, the problem has been studied with all the attention that experience has suggested, and the conclusion to which this expert arrives is, that the problem of aerial locomotion no longer presents any serious difficulties, that the theory is satisfactorily established, and that one may venture to proceed to execution. Neither does size offer any insuperable objection to this optimistic view. He calmly contemplates the manufacture of an aerostat 300 metres long by 30 broad, dimensions which approach, if they do not exceed, those of an Atlantic liner. An historical sketch of the progress of meteorology closed the sitting.

At the second meeting, M. Lancaster gave an account of the observations on the velocity of the wind in Belgium. In the main the author agrees with the results to which M. Hann, of Vienna, had been previously led. The paper, which is of great interest, appears in full in an annexe, forming the second part of the *Compte rendu*, being the memoirs presented to the congress. Another paper, to which we give only a brief reference here, is from M. Ventosa, astronomer at the Observatory of Madrid. It has for its object the determination of the direction of wind at high levels from observation of star images, and also that of the sun. This subject came before the meteorological committee at Upsala, and seems to have been well received, since M. Ventosa was encouraged to continue his observations (see NATURE, vol. li. p. 185; also p. 179 of this number).

THE HUXLEY MEMORIAL.

THE following is the official report of the first meeting of the General Committee, formed for the purpose of establishing a memorial to the late Right Hon. T. H. Huxley, P.C., held in the Museum of Practical Geology, Jermyn Street, on Wednesday, November 27, 1895. Present—250 Home Members of the General Committee. His Grace the Duke of Devonshire, K.G., in the chair.

The Duke of Devonshire, in opening the proceedings, said:—

My Lords and Gentlemen,—It would be in the highest degree presumptuous on my part if I were to attempt, in the presence of so many distinguished men of science as I see around me, to offer anything in the nature of an estimate of the character and work of Prof. Huxley, or of the services which he has rendered

to science, either as an original investigator or as an exponent. As, however, I presume that it is as the official head of the Science and Art Department that I have been asked to accept the chairmanship of this Committee, it may be proper that I should open the proceedings by a very brief statement of the official connection of Prof. Huxley with that Department, although I am perfectly aware that the services which he rendered to that Department, valued and valuable as they were, form but a very small part of the work which Prof. Huxley did for science; which, both during his lifetime and since his death, has been so fully recognised by every scientific man in the country.

Prof. Huxley, immediately after leaving the Navy, in which he commenced his career, succeeded in 1854 Prof. Forbes, as Lecturer on Natural History in the Central School of Science in Jermyn-street. This school subsequently became the Royal School of Mines. It was transferred to South Kensington in 1881, and there merged in the Royal College of Science. Prof. Huxley was the first Dean of the College, and on his retirement from the public service in 1885, he was requested by the heads of the Department to retain the office in an honorary capacity. This he did, to the day of his death; attending the meetings of the Council, and giving assistance in other ways. He was also Honorary Professor of Biology in the College, retaining a general charge of the biological section. While Professor at the College he developed his system of biological teaching—which has had so marked an influence on biological teaching in all parts of the world. On his retirement in 1885 he presented to the College the large and valuable collection of books on natural history which he had formed. The room which he occupied was, by the authority of the Lords of the Committee of Council on Education, devoted to a Huxley Biological Laboratory for research, and it is in constant use by advanced students of biology. A scholarship has been endowed in connection with the College, and the history of that endowment may be of some interest. Prof. Huxley on one occasion met in society Miss Marshall, the daughter of Mr. Matthew Marshall, for many years Chief Cashier of the Bank of England, and in consequence of a conversation which she had with Prof. Huxley on that occasion, she left to the Department a large number of books and instruments and, in addition, a bequest of £1000, from the proceeds of which the scholarship referred to has been endowed.

Prof. Huxley was, for more than forty years, intimately connected with the Science and Art Department. The Jermyn Street Museum, in which we are met to-day, is a section of that Department, and both in this lecture-theatre and in the classrooms upstairs, Prof. Huxley for many years delivered his lectures.

It was almost my first duty—and I need not say, my painful duty—after I became President of the Council, to address (on the part of the Committee of Council on Education) a letter of condolence to Mrs. Huxley, in which the Committee placed on record its high appreciation of the services to science and art rendered by Prof. Huxley in the capacities to which I have referred, and in addition, on many inquiries by Royal Commissions, in which he had taken part. I am quite aware that the time of those who are here is valuable, and I shall, therefore, not detain you any longer, but must leave to others the duty of expressing the recognition of the whole of the scientific world of the brilliant life and labours of Prof. Huxley. I have thought, however, that this brief reference to the official side of Prof. Huxley's career might not form an inappropriate introduction to the wider view of his work and of his character, which it will be the duty of those who are to follow me to present to you.

Prof. M. Foster (Joint Honorary Secretary of the Provisional Committee), after referring to a number of letters expressing regret at being unable to be present at the meeting, gave a brief history of the movement for establishing a memorial, as follows:—

Very shortly after the death of Prof. Huxley, a few of his personal friends met together in the rooms of the Royal Society; they thought they would be carrying out the wishes of all by promoting such a memorial, and invited a number of representative and influential persons to meet to consider the matter. They met, and it was then thought desirable to take further steps; they therefore constituted themselves a Provisional Committee, and sent out invitations to a very much larger number of persons to form a General Committee. These invitations were very cordially received, and, among others, we had the pleasure of hearing from H.R.H. the Prince of Wales that he would join the Committee, and would, further, accept the duty of Honorary President. At that time the summer was too far advanced to take any active steps, and the meeting of the General Committee was postponed until the present date. In the meantime we approached his Grace the Duke of Devonshire, asking if it would be his wish to act as Chairman of the Committee, and his Grace kindly accepted this duty. The Provisional Committee have given much time to the consideration of various suggestions made as to the form which the proposed memorial should take; and certain resolutions, embodying the decisions arrived at, will be submitted to you; and it is for you to decide how far they shall be carried into effect.

Lord Kelvin, P.R.S., then proposed the first resolution:—

"That it is desirable to establish a memorial to the late Right Hon. Thomas Henry Huxley."

He said:—As an original investigator in biology, Huxley has, by his life-long perseverance in working for the increase of natural knowledge, left to the world a monument more enduring than any bronze or marble in which his survivors may give material expression to their gratitude. Of his originality he gave early proof. Whilst still a student in Charing Cross Hospital, he made an exceedingly skilful and acute microscopic investigation of the structure of hair; he discovered a special structure, and described it in a communication to the *Medical Times and Gazette* with so much effect that, to this day, it is known as "Huxley's layer." That was something for a young medical student to have done. His indomitable resolution to go on with work; his attraction to original investigation—an irresistible passion of his through life—was manifested from beginning to end. Soon after his technical school education in medicine was completed, he went away as medical officer to the *Rattlesnake*, on a four years' cruise. Happily, his medical duties left him some leisure; that leisure he employed in a series of most important investigations in natural history, which has made the cruise of the *Rattlesnake* celebrated in the annals of science. I cannot tell you how many memoirs he sent home from the *Rattlesnake*; some of them never came back; one he found on his return, in the shape of a memoir communicated to the Royal Society and published in its *Transactions*; it is known to all naturalists, and is admitted to be a very valuable and important paper. Several other papers were sent, including one very important paper—although it only occupies half a page of the Report of the British Association—dealing with the blood corpuscles of certain marine animals picked up in the surveying work of the *Rattlesnake*. These first works done, not in a scholastic manner as a thesis for a Degree of Philosophy, but simply from the innate fire and determined purpose of the worker, were but the beginning of a long series of memoirs which soon made the name of Huxley famous throughout the scientific world. He was very early recognised to be one of the first biological investigators of the day, and the value of his work will be declared to you by others who know thoroughly the merits of the work and the wants which that work supplied in natural science. They will tell you that his work in Comparative Anatomy was of very great value indeed; that he almost created a new era in biological science, by the great advances that he gave to the new Morphology. He carried out and extended, in the most admirable and valuable manner, the work of Von Baer and Johannes Müller, tending in this direction, and now we have—what medical students and students of natural science in Huxley's student-days could learn nothing of in school or university—we have Morphology and General Biology taught regularly and systematically; and, I believe, I may safely say, not only to the great benefit of medical science, but to the great benefit of science in general; to the great benefit of those who are studying science for the sake of knowledge and of opening their minds, and of understanding the grandeur and beauty of nature and what lay underneath it.

Huxley's work was not confined to miscroscopic examination and the dissection of plants and animals—comparative anatomy generally, including the vegetable world—although it began with that. He entered on the subject of geology and of palæontology in a manner which has left fruit of a most enduring character, especially in palæontology: his tracing of relationships, and his philosophical reasoning regarding these relationships, which led him to find in the rocks the ancestors of many creatures now living on this earth, and his contributions to the great and newly-developed science of evolution, are so well known that I need only name them to at once remind you

who have entered on that subject how much science owes to Huxley. But Huxley was not a man who was only a specialist, simply content to investigate his special subject in the complete and thorough manner which characterised all his work. From the very beginning he had a mind that must extend into philosophic thought. His moral lessons from his biological work extended even into the field of politics, and his contributions to thought in respect of theology, in themselves are such as to put Huxley's name and fame in a very high position indeed, as a man thoroughly determined to give all the benefit he could to mankind. As a worker who gives his life, who sacrifices his health, who sacrifices his time, who gives up everything for the advancement of science; but, as he tells us himself, with an object which he felt to be even greater than the advancement of science, the promotion of the welfare, moral and material, of mankind: who deserves a memorial or a monument better than Huxley?

The Right Hon. A. J. Balfour, M.P., in seconding the resolution, said:—

I gladly welcome the opportunity which the managers of this meeting have given me of lending such support as I can to the proposals that have been laid before you, for Prof. Huxley was a man who had many titles to our gratitude. I need not dwell upon what your Chairman has said with regard to Prof. Huxley's services as a teacher, or to the services he constantly gave to the Government of the day in lending his great talents to any investigations that were required of him. But putting all these relatively subordinate matters out of mind, Prof. Huxley, as a man of letters, and as a man of science, surely deserves from his fellow countrymen some permanent memorial. Every one whom I am addressing is probably well acquainted with those works which, quite apart from the matter which they contained, have earned for their author the reputation of being a master of clear, lucid, and vigorous exposition, not easily to be matched in the whole gallery of our literature. Lord Kelvin, in the observations which he has just made to you, and others far more qualified than I am to speak on such subjects, who will address you before the meeting closes, will give some indications of the great extent of the scientific labours and discoveries which will always be associated with Prof. Huxley's name. For my own part, however, if I were to try to choose among the many titles to our gratitude which he possesses, I am not sure that I should seek for it either in his literary performances, distinguished though they were, or in the series of scientific discoveries which have given him so distinguished a place among English biologists. It appears to me that Prof. Huxley has another claim, at least as great upon the gratitude of those who were born in the generation subsequent to that of Darwin. I take it that the great scientific fact of the latter half of the nineteenth century is the establishment of the doctrine of Evolution upon a scientific basis. I do not pretend to say for a moment, that in his labours in that direction, Prof. Huxley could be put upon a level with the great scientific originator of the doctrine of the Origin of Species, or with a very different and very eminent man—Mr. Herbert Spencer, who occupies so remarkable a position upon the borderland between science and philosophy. But this, I think, may truly be said, that in the critical period of scientific history which followed the publication of the "Origin of Species" in 1857, the man who did, perhaps, more than any other to stimulate public interest in the subject, to bring into line all the younger scientific thinkers of the day, to inspire them with his ardour, and with his convictions, was, probably, Prof. Huxley. That is no small title to fame. If it be the fact, that it is now the common privilege of all educated men to look at this material world in which we live, from the evolutionary standpoint, we owe it not merely to the great original investigators who started the theory, but to those who, like Prof. Huxley, did so much by their scientific discoveries to support it, or even more by their scientific preaching and their example, to spread it among all classes of their fellow countrymen. There were other questions never far absent from the mind of Prof. Huxley, as any one who knows his work will admit, as to which he has left few positive results, and concerning which differences of opinion exist; but there is, or there ought to be, no difference of opinion as to that great claim on our consideration which I have mentioned, and this, even if it stood alone, dissociated from his literary and strictly scientific work, it would, in my judgment, be quite sufficient ground for our using every exertion to carry into effect the resolution which it is my honour now to second.

Lord Playfair, in supporting the resolution, said:—

It is scarcely necessary to say one word in regard to the eminence and the scientific position of Prof. Huxley, but it has been my privilege to be associated with him in many of his undertakings and labours as a public man. I was a Professor with him in this Institution, and had the pleasure of having him as a colleague in many public inquiries and on various Royal Commissions for the benefit of the public. In higher education, the Scotch University Commission benefited by his wise counsel and breadth of culture. The present position of technical education also owes much to the advocacy and the scientific lectures which Prof. Huxley gave through the country. There is one labour in which to the time of his last illness, I had great pleasure in being associated with him—that was in the establishment of scientific scholarships of £150 a year in almost every college and university, not only in the United Kingdom, but in the Empire of India and throughout all our Colonies. That was a subject very dear to Prof. Huxley's heart, and although he was not much engaged in the executive part of it—which fell to my share as a Commissioner for the Exhibition of 1851—Huxley was a much-valued adviser in all matters relating to the establishment of these scholarships. They are all Research Scholarships, and are now exercising a benign and important influence over the science education of our great Empire. One whole autumn I had the pleasure of being in a gunboat with Prof. Huxley—being both on the Royal Commission for the examination into the fisheries of the British Coasts—and it is scarcely necessary to say he was a most active and valuable member of that Commission, both from his scientific knowledge and in estimating the value of the evidence of the fishermen in various parts of the fishery coasts of England. I do not, in speaking of his labours as a public man, wish to overrate them in comparison with his scientific work. On the contrary, I think discoveries in abstract science are of far greater importance to humanity than any labours performed for the particular generation in which the man lives. Still his public work had a great effect in making the name of Huxley popular and beloved by the people of this country; and we are entitled to ask the people for whom he has done so much in his generation—for he has left England better than he found it—to join us in making a memorial worthy of this great man whose memory is a possession dear to the country.

The resolution was then put to the meeting and carried unanimously.

Sir Joseph Hooker (Chairman of the Provisional Committee) moved the second resolution:—

"That the memorial do take the form of a statue, to be placed in the Museum of Natural History, and a medal in connection with the Royal College of Science, and that the surplus be devoted to the furtherance of biological science in some manner to be hereafter determined by the Committee, dependent upon the amount collected."

He said: As Chairman of the Provisional Committee, appointed to consider the question of a fitting testimonial to the great services to science and education of Mr. Huxley, I have the honour of saying a few words in regard to the result of its deliberations. Before doing this, you must allow me to express the singular honour I felt in being appointed to that position of Chairman, not only because of the great and important duty, but especially because of my great, long, and enduring affection and regard for Prof. Huxley. We both entered the public service as assistant surgeons and volunteer naturalists in the Royal Navy. Before Prof. Huxley went out in the *Rattlesnake*, the choice lay between us for the appointment to that vessel, and, fortunately, the choice fell upon him. Immediately upon his return a strong friendship sprang up between us, which has lasted forty-five years, throughout which he has been one of my staunchest and firmest friends. This friendship has affected me through life, and I owe a great deal of my success in scientific life to the advice, the stimulus, and the example which Prof. Huxley set me during a long career. After what has already been said by previous speakers, it would be a work of supererogation for me to go into any detail as to the great value of the services of Mr. Huxley, whether to science or education. You will be pleased to hear that these are appreciated, even more abroad than in this country: although if pleased in one sense, I

am afraid you will not feel satisfied in another. In a notice put into my hands by the Secretary, I find the Committee includes over 700 names; a special feature of it is the high percentage of acceptances from foreigners, which exceeds that from home sources, but I hope this state of things will be speedily remedied. Many of the foreign acceptances have been accompanied by letters expressing the highest admiration for Mr. Huxley, and good wishes for the success of the memorial.

With regard to the duties of the Provisional Committee, I need not say there were a great many proposals laid before them. It is unnecessary to go through these proposals, but they received the greatest attention. They may be grouped under four heads:

(1) A statue to occupy a public position.

(2) The founding of Exhibitions, Scholarships, and Medals for Biological Research, &c.

(3) The founding of Lectureships, &c.

(4) The republication of Prof. Huxley's Scientific Publications, in a collective form.

This last proposal has, I am glad to say, been partly met by a most liberal offer made by Messrs. Macmillan, who are prepared to publish, at their own risk, in a collective memorial form, the scientific papers of the late Mr. Huxley, now scattered over the publications of various learned societies and periodicals, provided that the size does not exceed two or three volumes of royal 8vo.; all we have to do being to appoint some one to supervise this invaluable series of papers. With regard to the memorial, the Committee decided to recommend that it should take the form of a statue and a medal, as now set forth in the resolution proposed.

Mr. Leslie Stephen, in seconding the resolution, said:—

I must preface the few words which I have to address to you, by saying that I had to overcome a certain degree of reluctance in addressing myself to you to-day—I did, however, overcome that feeling—because I feel that I am under the stress of a strong sense of personal gratitude to Prof. Huxley. I knew him for, I think, nearer forty than thirty years, and during our intercourse it happened, more than once, that he was able to show kindness to me on occasions in which kindness is doubly valuable, and on which one acquires a considerable degree of power of discriminating between merely conventional courtesy, and the outpourings of a warm, cordial heart. One of these occasions happened only recently; and I have so keen a recollection of Huxley's kindness and cordial sympathy, that I could not refuse to come here to say a few words to-day. I know that I am only saying what is felt by all who knew him, that he was a man who was not only to be honoured for his intellectual power, but to be loved for his masculine and affectionate nature. But qualities of that kind are happily not so rare as to demand any public testimonial. Only when they are combined with others, it is not merely a duty, but a privilege to seize any occasion of paying what honour we can to their possessor. I will not, however, dwell upon them; and, still less, upon those claims of Huxley as an advancer of science, of which there are other incomparably superior witnesses present. There is one point on which I, perhaps, may say a word or two without presumption. I have had the misfortune to be compelled to devote the greatest part of my energies to books, and only to see facts through the distorting medium of literature. It fell to my lot lately to read through the collected works of Prof. Huxley, and when I came to the end I felt a conviction—which Mr. Balfour has already expressed—that when the history of his time comes to be written, Prof. Huxley will find a place not only among the leaders in the most characteristic movement of the time, but also as one of the very first writers of English. There are certain reasons, perhaps, why his claims in that capacity may not be acknowledged so quickly as they ought to be by the ordinary critic. Nobody, of course, can read his lectures without admiring the force and vigour of the great intellectual gladiator. One feels of his style what I remember Hosea Biglow says, in a different connection, that—"for putting in a downright lick betwixt the eyes of humbug, none could match it." But then the critic of the present day is apt to take account only of what he calls "form," and not to attend and to dwell upon the more evanescent and indirect, intangible facts of literature; he is apt to think that the facts state themselves, that the thing is so clear it does not want any particular skill to work it out. The argument, when it is set going, seems to evolve of its own accord, and then he criticises in the style of the famous gentleman, who said, of some great work, "I could have written it myself, if I had only had a mind to." The obvious retort was—"it was just *mind* that was wanted." And what a style like Prof. Huxley's—which calls no attention to itself, but just sets the argument plainly before it—what that shows is certainly the possession, in the first place, of a clear, logical understanding, which always goes to the heart of matter; but it shows also, I think, some other great qualities. One cannot help observing the love of fair-play, which prevents him from ever striking a foul blow, and his loyalty to his friends, which gives a glow and warmth to his style, in standing up for such a man as Darwin for example; and besides that, the unflinching love of truth, the hatred of throwing dust in other people's eyes or letting it obscure his own, and, finally, what has been most truly noticed already, his strong preoccupation with the greatest and deepest problems of the time which, however they may be solved, whether in his sense or any other, require to be approached in a manly, serious spirit, as he always approached them. These, as I take it to be, very shortly are the mental and moral qualities which will give to Huxley's writings a place not only in science, but in the best kind of English literature, and in that faith it gives me the greatest pleasure to be allowed to have the honour of seconding this motion.

The resolution was then put and carried.

Mr. Alma Tadema moved the third resolution:—

"That the persons named in the list which has been circulated do form a General Committee, and that the following twenty persons be selected to form an Executive, with power to elect its own Chairman, and to add to the number of the General Committee:—

SIR W. BESANT.	SIR J. LISTER, BART., P.R.S.
SIR J. DONNELLY, K.C.B.	PROF. J. N. LOCKYER, C.B., F.R.S.
SIR J. EVANS, K.C.B., F.R.S.	LORD RAYLEIGH, F.R.S.
SIR J. FAYRER, K.C.S.I., F.R.S.	MR. BRITON RIVIERE, R.A.
SIR W. H. FLOWER, K.C.B., F.R.S.	DR. P. L. SCLATER, F.R.S.
PROF. M. FOSTER, F.R.S.	LORD SHAND.
PROF. E. FRANKLAND, F.R.S.	SIR H. THOMPSON.
SIR A. GEIKIE, F.R.S.	MR. SPENCER WALPOLE.
SIR J. HOOKER, K.C.S.I., F.R.S.	THE RIGHT HON. SIR J. LUBBOCK, BART., M.P., K.C.B., F.R.S., *Hon. Treasurer.*
PROF. E. RAY LANKESTER, F.R.S.	PROF. G. B. HOWES, *Hon. Secretary.*"

He said:—It would be presumptuous in me, a painter, after all you have heard and all you know about the departed friend, to say any more to you as to why humanity owes so much to that giant of science. But you know that, in England, science and art are merged together. We have our department, and so I have a certain right to say a few words. As it has been already so rightly remarked, Prof. Huxley was a man of innate worth and energy: when you were in his presence you felt as if you were sitting in the sunshine, and sunshine is the life of an artist. Besides that, he loved art, and art flowed in his blood, as you know so well, because one of his daughters was a first-class artist.

Sir Andrew Noble seconded the resolution, which was carried unanimously.

Prof. G. B. Howes (Joint Honorary Secretary of the Provisional Committee) announced that the sum already received in donations to the memorial was £213, and that £344 more was promised, making a total of £557. The donations included £100 from Andrew Carnegie, Esq.; £100 from J. Allsop, Esq.; and £50 from the Marquis of Salisbury.

Sir John Evans proposed that a hearty vote of thanks be given to his Grace the Duke of Devonshire for his kindness in presiding at the meeting.

Sir J. Fayrer seconded the resolution, which was carried unanimously.

The Duke of Devonshire, in reply, said:—I can only say I am very much indebted to you for the cordial vote of thanks you have been so good as to pass to me. I need not repeat what I said in opening these proceedings—that I feel as fully as any one present can possibly do how entirely deficient I am in any claims of a personal character to occupy the distinguished position for which I have been selected. I think, however, it is perfectly right that some member of the present Government of the country should be associated with a movement of such national interest and importance as the present one, and I am aware that, as the Minister

who is responsible for the Education Department of Government, I am, perhaps, officially designated for this position. I need hardly say that I shall find it somewhat difficult to give very constant attention to the duties which will devolve upon the Committee. I trust, however, that the General Committee will be relieved of any work of a detailed character by the Executive Committee which you have just appointed. However, I can only assure you that any further services which I am able to give to this cause will be very cheerfully rendered, and I think I may conclude by congratulating you on the character of the proceedings which have taken place this afternoon. I assure you I feel it a very high honour indeed to have been permitted to preside on such an occasion, and over a meeting containing so many distinguished persons as those who have assembled here this afternoon.

The meeting then adjourned.

Since the meeting of the General Committee, two meetings of the Executive Committee have been held. At the first of these, at which Lord Shand accepted the office of chairman, it was reported that a number of foreigners of eminence had expressed a wish to be associated with the proposal to commemorate Mr. Huxley's distinguished services to humanity. It was resolved, in the first instance, to invite subscriptions from the members of the General Committee. At the second meeting, held on Wednesday last, it was reported that the subscriptions, which at the general meeting had amounted to £557, had been increased to about £1400, and it was resolved that a wider appeal for subscriptions should now be made to the friends and admirers of Mr. Huxley amongst the general public. The Honorary Secretary stated that in America committees were in the course of being formed to promote the realisation of an adequate Fund. The Committee resolved to communicate, by means of a Sub-Committee of their number, with Mr. Onslow Ford, R.A., who had the advantage of being well acquainted with Mr. Huxley, in reference to the statue, which it is proposed should be erected beside those of Darwin and Owen in the Natural History Museum, South Kensington. The extent to which the Committee may be able to carry out the other intended objects of founding exhibitions, scholarships, and medals for biological research and lectureships, and possibly in assisting the republication of Mr. Huxley's scientific works, will of course depend on the subscriptions which may now be received. These may be sent to the Treasurer, Sir John Lubbock, or the Bankers, Messrs. Robarts, Lubbock, and Co., 15 Lombard-street, E.C.; or to the Secretary, Prof. G. B. Howes, Royal College of Science, South Kensington.

The amount received to December 20 was £1535.

The court of the Fishmongers' Company, in consideration of the eminent and important services rendered by Huxley to the cause of technical education, has agreed to give a scholarship of £60 per annum to the City and Guilds of London Technical College, Finsbury, to be called "the Fishmongers' Company's Huxley Scholarship," to be held for three years by any scholar who has given evidence of high scientific attainments, to enable him to proceed to the Central College at Kensington.

RELATIONS OF THE WEATHER BUREAU TO THE SCIENCE AND INDUSTRY OF THE UNITED STATES.[1]

IT is a matter of much pleasure to me that I am allowed the privilege of speaking at a joint session of this Association—representing as it does within the confines of its admirable organisation the scientific thought of our country. This is the Mecca towards which annually journey all those who wish, each to contribute his mite to the sum of human knowledge; each inspired with an ambition to add even one flickering ray to the great luminous orb which to-day is shedding the benign light of wisdom even unto the uttermost recesses of the earth; subduing the barbarous instincts of man, and warming and invigorating into life the better impulses of his nature. Thus is civilisation advanced, and thus is humanity elevated to higher and higher planes of existence.

I hope to be a worker in the ranks of this great army, and as the science of meteorology can hardly be said to have passed beyond the embryonic state, I feel that the realms of investigation are boundless, and that the opportunities are correspondingly great.

As the Chief of the greatest meteorological system in the world, and with the power to control, under the direction of the Secretary of Agriculture, not only its executive functions, but the lines of future scientific investigation, I fully realise the great responsibility that rests upon me, and that at the bar of public and scientific opinion I shall, in the years to come, justly be held to a strict accountability for my stewardship.

Before considering the lines of investigation which can consistently be prosecuted by the Weather Bureau, it will be well to note the law which perscribes the duties of the Chief.

By an Act Congress approved October 1, 1890, Sec. 3, Statutes at large, Fifty-first Congress, p. 653, it is provided:

"That the Chief of the Weather Bureau, under the direction of the Secretary of Agriculture, on and after July 1, 1891, shall have charge of the forecasting of weather, the issue of storm warnings, the display of weather and flood signals for the benefit of agriculture, commerce and navigation, the gauging and reporting of rivers, the maintenance and operation of sea-coast telegraph lines, and the collection and transmission of marine intelligence for the benefit of commerce and navigation, the reporting of temperature and rainfall conditions for the cotton interests, the display of frost and cold wave signals, the distribution of meteorological information in the interests of agriculture and commerce, and the taking of such meteorological observations as may be necessary to establish and record the climatic conditions of the United States, or as are essential for the proper execution of the foregoing duties."

It will be seen that the main object for the existence and continuation of this Bureau is to give warning of the approach of storms, and therefore that the proper line of investigation should be for the purpose of determining the true philosophy of storms. The goal to be striven for is the improvement of weather forecasts, and surely one of the pre-requisites to determine coming events is a thorough knowledge of existing conditions.

To those who have read every important treatise on meteorology, and who have studied every text-book on the subject, it is painfully patent that we are extremely ignorant of the mechanism of storms, of the operations of those vast and subtle forces in free air which give inception to the storm, and which supply the energy necessary to accelerate cyclonic action when formed, or to disperse the same when fully in operation. We know that great atmospheric swirls in the shape of high and low pressure areas alternately drift across the country at intervals of two or three days; that the atmosphere flows spirally into the cyclonic or low-pressure system and outward from the anti-cyclonic or high-pressure system, that the in-drawn east and south winds on the front of the storm are warm, and that the inwardly-flowing north and west winds are cold.

The theories of Redfield, Espy, Loomis, Ferrel, and others, teach that our great storms are composed of immense masses of air gyrating about a vertical or nearly vertical axis, drifting eastward, and at the same time drawing in warm easterly currents at the front, and cold westerly currents at the rear; that the commingling of these two as they rise to greater and greater elevations, near the regions of the cyclonic centre, throws down volumes of rain or snow; that as precipitation occurs with the ascending currents, the heat of condensation energises the cyclonic circulation; that the air at the centre of the storm is relatively warm, is rarefied by centrifugal force, and by reason of less density, rises to a great elevation, and in the upper regions of the atmosphere flows away laterally to assist in building up high-pressure areas on either side.

The high and low pressure areas are supposed to be carried eastward by the general easterly drift of the atmosphere in the middle latitudes, somewhat as eddies are carried along by water in a running stream.

But, unfortunately for the complete accuracy of these theories, the forecaster often finds heavy downpours of rain without any cyclonic circulation, and no convectional system in operation; again over immense areas of country, especially in the Rocky Mountain region, for many months in the year condensation occurs not at all in the warmer easterly currents flowing into the storm centre, but almost exclusively in the westerly portion of the storm area, where the cold north and west winds are flowing in.

Again, many investigators to-day have good reason to doubt

[1] Read before the American Association for the Advancement of Science, at the Springfield Meeting, by Prof. W. S. Moore, Chief of the U.S. Weather Bureau. (Reprinted from *Science*.)

that the centre of the storm is warm to any great elevation, or that cyclonic circulation obtains to the top of the air.

In outlining, in a rough and general way, the line of investigation which in my judgment promises to give the most prolific results, not only to the cause of meteorological science, but to the making of more accurate forecasts for the benefit of agriculture and commerce, I will say that we have been for years taking our measurements at the bottom of this great ocean of air, while the forces which cause the formation of storms, and which influence their intensity and direction of motion, operate at great elevations, or are extraneous to our earth. It therefore seems imperative that systematic exploration should be made of the upper air. Balloon ascensions should be made in the several quadrants of the cyclonic storm, and also at the centre thereof, especially when rain is falling and the barometric gradient is steep. It is especially important to know the level at which condensation ceases, the depth of the cloud stratum, the temperature gradient, the air pressure and humidity, to a height of four or five miles. Skilled aëronauts with complete and accurate instruments should be placed in the region of severest action at the season of the year when storms are most frequent. They should be held in readiness until the approach of storms typical of cyclonic action, and then from the central office, where the movement of the storm is being carefully watched on the daily synoptic chart, they should be given telegraphic orders to ascend, and their ascensions should be so timed as to secure accurate readings at great elevations throughout the several quarters of the storm. It is believed that information thus secured will establish something like an approach to the true philosophy of storms, in contradistiction to the very imperfect theories which too often are hastily approved as demonstrated principles. Instead of erecting a cumbersome superstructure upon the sand, let us endeavour to lay a corner-stone upon which to erect something exact enough to be called a science.

In winter the great high-pressure areas which constitute our cold waves should receive the same thorough exploration. Readings at Pike's Peak or Mount Rainier might be useful in this investigation, but they are too far removed from the general track of storms and cold waves to furnish the full information desired.

Upper-air explorations may be accomplished by a train of kites carrying automatic instruments, by captive kite-balloons which may be forced nearer and nearer the zenith with increasing wind velocity, or by the ascension of trained observers in free balloons. We must strive for the perfection of appliances and instruments which will, at no distant day, enable us to present to the forecaster the charted synchronous meteorological conditions prevailing at high levels and covering a great area. Mr. McAdie, at Washington, has secured recently some good records with kites at elevations from 1000 to 2000 feet.

Systematic exploration of the upper air, with a continuation of the studies begun by Prof. Bigelow of terrestrial magnetic forces as induced by the solar magnetic field, will be the line of investigation prosecuted during the next two years, and from which it is hoped that results satisfactory to the practical as well as the theoretical man may be obtained.

The Secretary of Agriculture is in thorough sympathy with all lines of research which can be legally carried on under the Act of Congress constituting the Weather Bureau, and which promise to give results useful to the people.

Harmonious co-operation between the practical worker and the scientific investigator is essential to success. Too often they have found themselves picking out diverging paths. In the future they will work on parallel and converging lines, and not far removed from each other, and the result, I am confident, will be beneficial to all. In a great system like ours, each worker must be justly recognised for the merit that is in him, whether he be a skilled scientist or an able executive officer, and he should be given his proper place as an integral part of the great whole which constitutes the efficient Bureau.

A brief retrospect of the forecast work may not be without compensating results in our efforts at future improvements.

Forecasts were begun in the United States about twenty-five years ago, and have, during the past decade, become of such benefit to the many and diversified interests of the country that, with one accord, the people now acknowledge their value, and applaud all efforts to improve and extend their usefulness. Fifty million dollars is a low estimate of the value of property placed in jeopardy by one West Indian hurricane sweeping up our Atlantic coast

Predictions were first called "probabilities," and were made for districts, each comprising several States, and included a prediction as to the probable change in barometer. Later the prediction as to barometer was omitted. Forecasting by districts was soon shown not to be specific enough as to boundary, and the designations applied were not well understood by the people; hence forecasting by States was adopted.

Forecasts were made only at the Central Office at Washington, and the local observers were allowed to disseminate no other, nor to give public expression to any opinion of their own which might be construed into a forecast. Considering the very limited training of the observers, and the lack of all chartered meteorological conditions for their study and enlightenment, the wisdom of that regulation could hardly be questioned.

With the transfer of the Weather Bureau to the Department of Agriculture, came the inauguration of far more liberal and progressive ideas. The office of Local Forecast Official was created for such observers as had shown special fitness for forecast work, and they were assigned to duty at the more important agricultural, commercial, or maritime centres, with instructions to carefully study the local climatology of their sections, so that products that are indigenous to limited areas, or interests which are of special importance to particular sections, might have such application of the weather forecasts as the intimate personal attentions of a competent local official could give.

The changes enumerated have been carefully tested and found to be beneficent in purpose, and worthy of continued and permanent application. Thus has the forecasting system of to-day slowly developed during the past twenty-five years. Is it not the essential feature of the Weather Bureau? Is it not the nucleus around which all departments of thought and study must rotate and become auxiliary, if the original intent of Congress, made manifest by the establishment of a national storm-warning system, is to be carried forward to as successful an operation as the present knowledge of the physics of the air will permit? It is hoped that discoveries may be made relative to the controlling and modifying forces of storms which shall raise the standard of forecasting accuracy attained by our most expert officials, who have had all the benefits to be derived from many years of patient and intelligent observation of storms, from the time of their inception in, or entrance within our daily observed and charted territory, until they have been dissipated or have passed eastward beyond our range of vision.

It may be well to consider what class of forecasts can be most successfully made by our more or less empirical methods, the object being to extend the work along such lines of activity as promise the most beneficial results.

As to this proposition it is doubtless conceded by all that when pronounced high and low-pressure areas dominate the weather conditions and the changes in wind, temperature and weather are characterised by such force and degree as to render them destructive to lives and property, a forecaster of average ability and well-balanced judgment is able to make nearly or quite as accurate a forecast as when the air pressure is quite uniformly distributed and all changes of weather are so slight as to be of no importance.

If, then, a destructive frost or cold wave can be predicted as easily as a change of a few degrees in temperature, and if the coming of high winds and gales are as easily foretold as that of a gentle zephyr, it is evident which class of forecasts should receive the greater attention. The public care comparatively little for predictions of moderate changes, and but little credit attaches to the Bureau when such forecasts are verified; but when great heat, cold waves or violent winds are on the programme, a vital interest is felt in the subject, and the accurate forecasting of such conditions is the gauge by which the public measures the usefulness of the Bureau.

Horticulturists and the growers of tobacco and cranberries realise the vast benefit to be derived from accurate frost predictions, and I will give a brief statement of what I believe to be original ideas introduced into the making of frost forecasts while in charge of the State Weather Service of Wisconsin, a State including within its domain the largest area of cranberry marshes in the world, and also including an extensive area devoted to the cultivation of tobacco. Heretofore I believe that only the air conditions have been taken into consideration in the making of frost forecasts—such as pressure, temperature, relative humidity, cloudiness, and wind velocity. As a result of my investigations, systematically prosecuted for three years, I found that the conditions of the soil were equally as important as those of the air.

When the high-pressure area is moving in from the west, clear and colder weather anticipated, with the probability that the early morning temperature will permit the formation of frost—the most important elements to be considered, in determining whether or not frost will occur injurious to growing crops—are as follows:

(1) Has rain recently fallen, and what is the condition of the soil relative to the amount of moisture contained?

(2) What are the natural properties of the soil relative to the slow or rapid loss of heat by radiation?

(3) To what degree of heat has vegetation been subjected during the period immediately preceding?

The early fall frost injurious to tender crops occurs with the observed town or telegraph minimum temperature ranging from 40° to 50°, because, when the early morning temperature in the town falls much lower than 40°, it is usually so late in the season that all crops are gathered, or, if not gathered, they have been destroyed ere this condition arrives. At the time, then, that frost-warnings are of the most benefit, we have to deal with the air at temperatures considerably above the freezing-point, and to recall that a deposition of frost requires that the temperature of the top soil, or that of vegetation, be reduced to the freezing point. This, of course, is accomplished by conduction and radiation of heat, which takes place more rapidly from the soil and vegetation than it does from the lower stratum of air to the higher.

Anything that will seriously interfere with a rapid loss of heat after nightfall will tend to prevent the formation of frost. Moisture does this, and if the soil be well charged it partakes greatly of the stability of water as to temperature, and cools but little, if any, below the temperature of the superincumbent air, and no frost will occur even though all other favourable conditions of clearness, gentle winds, and cool air obtain. Even a small amount of moisture, say one-half inch of rainfall, will give ample protection if well distributed and precipitated within the twenty-four hours previous. But when severe drought conditions are prevalent, injurious frosts may occur when the telegraphic temperatures do not show a reading within ten degrees as low as in the first case.

I believe that, when estimating the probability or severity of frost, sufficient weight has not been given to the dryness or wetness of the soil, and the resultant dissipation or conservation of heat, and I call special attention to the point as one of the means for improving the forecast.

I have in mind two typical cases. In the first a high-pressure area attended by clear and cool weather drifted from the westward until it covered the State. No rain had fallen with the passage of the low-pressure area immediately preceding it; hence the ground was in excellent condition for the rapid loss of heat during the night, and a consequent lowering of the temperature of vegetation to the freezing point. Considerable damage was done to cranberries in unflooded marshes. In the second case a high-pressure area of slightly greater weight and slightly lower temperature covered the region about ten days later, but it was preceded within a few hours by a light but well-distributed fall of rain, averaging about one-half an inch, and no frost occurred. In both cases the wind was gentle from the north-west, and the nights were clear. With slightly lower air temperature and higher barometer in the second condition, heavier frost would have occurred than in the preceding case, had it not been for the thinly spread moisture of the timely rain conserving heat at the surface of the earth.

Might not this principle be carried further in the improvement of the forecast? Assuming that the caloric energy of the sun is a constant factor, the earth receives each year the same amount or intensity of heat, and as the atmosphere is warmed mainly by contact with or radiation from the earth, seasonal variations of temperature which are marked departures from the normal might result from abnormal terrestrial surface conditions with respect to the conservation of this constant solar energy over large continental areas. Here the excessive or deficient rainfall during the preceding seasons should receive careful consideration. The subject is one that requires deeper and more detailed investigation than the length of this paper will permit.

I find that the minimum temperatures in cranberry marshes during abnormally dry seasons often fall 15° below the temperatures telegraphed from the cities and towns within a few miles of the marshes. This is due to the fact that when the loose, spongy peat, of which the marsh is composed to the depth of several feet, has dried out, the radiation of heat during the night is very rapid, and is not counterbalanced by conduction and connection from the marsh. The temperature, therefore, in cranberry marshes is at all times much lower than that which obtains in marshes composed of heavy black muck, where it preserves a more equable condition, such as is common to air resting over a considerable body of water. A dry cranberry marsh does not, therefore, enjoy that immunity from frost enjoyed by wet marshes and watery lands. But when the ditches are flooded from the reserve water supply on receipt of a frost warning, the water quickly percolates through the peat composing the marsh, and the rapid loss of heat by radiation is checked and the frost averted.

The amount of heat to which vegetation has been subjected immediately before the frost condition, and the temperature under which it had made its growth, will in a great measure determine the extent of damage to ensue.

By carefully considering the principles herein enunciated, I will say that in 1894, twelve out of fourteen official forecasts of frost were fully verified—a much greater percentage of accuracy than has ever been attained by simply considering air conditions alone.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ON Friday, the Chancellor of the Exchequer received at the Treasury a large deputation in support of a memorial praying that increased aid may be given to the English University Colleges, ten in number, and to University College, Dundee, which at present receive among them an annual grant of £15,000. Sir M. Hicks Beach, in reply, said there was no question that the existing grant of £15,000 would be continued; but he thought that in accordance with the recommendations of two Parliamentary committees a competent inspector should be appointed to visit annually each college receiving a grant, and report on its efficiency, its success, and its financial position. Till such an inspector should have reported, he did not think it possible for him to consider the increase of the grant.

IT is satisfactory to be able to note that the question of the education of mine managers, assayers, and engineers in Australia is actively discussed in the most recent Government reports on mines for several of the Colonies. In Victoria, mining schools have long been established at Ballarat and Bendigo, with branches at the more important mining centres in the Colony. Certificates of competency to act as mine managers are given by these schools, although the holding of such by mining engineers is not compulsory by law. In like manner in Tasmania, similar certificates are given after a Governmental examination. As the Under-Secretary for Mines of Queensland observes in his latest annual report, "the implication is that a certificated mining manager is preferable in the eye of the law to one who has no such credentials." In 1893 a school of mines in connection with Sydney University was founded by the New South Wales Government, and £10,000 spent in the erection of a suitable building, which has just been completed. The teaching staff has been formed at a small cost by utilising the services of the professors paid by the University, and lectu es and practical instruction are now being given in chemistry, metallurgy, assaying, geology, mineralogy, and all branches of mining to an increasing number of students. Up to the present Queensland alone, among the more important Colonies, has established no mining school; but, State aid having been p omised to well-supported schemes in any mining centre, the reproach will probably soon be removed. Indeed, some progress has already been made towards establishing a technical school at Brisbane. With regard to the effect of such schools, the Under-Secretary of Mines for New South Wales remarks, in his Report for 1894: "It is hoped that the establishment of the School of Mines will result in the gradual improvement in the methods of mining, as practised in this Colony, by providing a class of managers who will have had the advantage of a thorough scientific training, and who will only need a few years' practical experience to qualify them as mining engineers of the highest efficiency. The ultimate result must be an increased development in the mining industries of this country." In view of this feeling on the part of the Government officials of the various Colonies, it is evident that the compulsory possession of a certificate of competency by Australian mine managers is almost within sight.

SCIENTIFIC SERIALS.

American Journal of Science, November.—On the wave-length of the D_3 helium line, by A. De Forest Palmer, jun. The definition and intensity of this line varied greatly from day to day. The best combination of intensity and definition was obtained by avoiding prominences and working only on very clear days. The average for seventeen series of measurements was 5875·939 ± ·006.—Some additional notes on argon and helium, by Edwin A. Hill. The conclusion that argon is monatomic depends upon the correctness of three assumptions, viz., that a gas, with little or no rotational energy, must be monatomic; that the ratio of the two specific heats of 1·67 proves the gas to have no rotational energy; and that the ratio of the two specific heats is correctly determined. In choosing between the two alternatives of a diatomic gas without rotational energy or a free atom devoid of chemical affinity, the presumption is strongly raised that it is not a monatomic gas, but diatomic and chemically inert because the two atoms of the molecule are very strongly bound together. There is not much doubt that helium is a mixture, and if anything can be argued from the analogies between argon and helium, argon is a mixture likewise.—Recent progress in optics, by W. Leconte Stevens. Part II. This concluding portion of the presidential address deals with colour photography, with recent researches on the spectrum and on polarised light, and with colour sensation.—Effect of the mutual replacement of manganese and iron on the optical properties of lithiophilite and triphylite, by S. L. Penfield and J. H. Pratt. The transition from $LiMnPO_4$ to $LiFePO_4$ is marked by a considerable change in the optical characters of these isomorphous minerals. With an increase in iron there is an increase in the indices of refraction, and also the divergence of the optical axes changes rapidly.—The reduction of selenic acid by hydrochloric acid, by F. A. Gooch and P. S. Evans, jun. A solution of selenic acid is boiled in hydrochloric acid, and if the solution is not too dilute the reduction is obtained in a few moments. The hydrochloric acid must form at least 30 per cent. of the entire solution. The solution should be boiled until all the chlorine is expelled, but must not be allowed to fall below two-thirds of its original volume.—Reduction of selenic acid by potassium bromide in acid solution, by F. A. Gooch and W. S. Scoville. When intermixed with sulphuric acid and potassium bromide, selenic acid liberates bromine in proportion to the excess of acid, the bromide, and the elevation of the temperature. On boiling, the bromine is evolved and may be collected in potassium iodide, and the iodine thus set free may be determined by standard sodium thiosulphate and taken as the measure of the bromine distilled.—Restoration of some European Dinosaurs, with suggestions as to their place among the Reptilia, by O. C. Marsh. The geological positions of *Compsognathus* and *Scelidosaurus* are fully determined, but that of *Hypsilophodon* and *Iguanodon* is not so clear. The latter are found in the Wealden, which is usually considered to be Cretaceous, but might as well be classified as Upper Jurassic.

The numbers of the *Journal of Botany* for November and December are chiefly occupied with papers on descriptive botany. Mr. D. Prain completes his account of the genus *Argemone*, and Herr R. Schlechter his *Asclepiadaceæ Elliotianæ*, and describes also two new genera of the order, from Madagascar and from Angola.

SOCIETIES AND ACADEMIES.

London.

Royal Society, November 21.—"On the Gases obtained from the Mineral Eliasite." By J. Norman Lockyer, C.B., F.R.S. (Received August 6, 1895.)

Observations have been made of the gases obtained from the mineral eliasite heated *in vacuo*, in the manner which I have described in a former paper,[1] and, in addition to lines of known gases, others have been noted, for which no origins can be traced, at the following wave-lengths:—

Ångström.	Rowland.
6121·4	6122·4
6064·6	6065·7
5990·2	5991·2
5874·9	5875·9 (D_3)
5845·7	5846·7
5428·8	5429·8
5403·1	5404·1

[1] *Roy. Soc. Proc.*, vol. lviii. p. 68.

The wave-lengths of these lines have been determined by means of a Steinheil spectroscope having four prisms, comparisons being made with adjacent metallic lines, and the positions interpolated by micrometric measurements; the accuracy may perhaps be taken to be within 0·1 tenth metres. Other lines have been noted, but they are not included in the list, for the reason that their wave-lengths have not yet been determined with the dispersion stated above.

Of the lines in the foregoing list, six are in all probability coincident with chromospheric lines, as shown in the following table, which also indicates the frequencies and brightnesses of the lines according to Young:—

Wave-length of Chromospheric Lines.

(Angström's scale).	(Rowland's scale).	Frequency.	Brightness.
6121·2	6122·4	5	3
6064·5	6065·7	5	2
5990·0	5991·6	10	4
5874·9 (D_3)	5875·9	100	90
5428·8	5429·9	8	3
5403·1	5404·1	5	3

It is important to point out that all these lines do not appear in the spectrum at the same time. For instance, in the first two specimens of the mineral no trace of D_3 was noted, but in the third portion examined, all coming from the same specimen, D_3 appeared as a pretty bright line. Again, as in the case of a previous operation on bröggerite,[1] in one experiment with eliasite the products of distillation, collected in four stages, gave different spectra.

These facts seem to indicate that the gas obtained from eliasite is either a compound or a mixture of gases, just as is that obtained from bröggerite according to former experiments.

It is also to be remarked that among the lines in the eliasite spectrum, those at 6122·4 and 6065·7 have been recorded in the gases obtained from cleveite, and 6122·4 has also been noted in the gas obtained from gummite.

It seems to be more than probable, therefore, that the lines observed in eliasite indicate a new gas, in some way associated with those given off by cleveite and bröggerite, and the fact that D_3 is not necessarily present in the spectrum, furnishes an additional argument in favour of the view that the gas obtained from cleveite or bröggerite is complex.

Addendum. Received November 18.

The results in the foregoing paper depend upon eye observations on the red end of the spectrum. Since it was communicated to the Society the blue end has been investigated photographically. Many specimens of eliasite have been distilled, and numerous photographs of the spectra of the gases given off have been taken.

The work has been rendered difficult by the very small quantity of what I believe to be a new gas, and the large quantity of carbonic acid, nitrogen, and hydrogen given off from the mineral. Attempts have been made to get rid of the known gases, in order to make the lines in the new gas better visible, and then the amount of gas was in most cases very small and at times admixed with argon produced by the sparking.

The photographs have been measured and reduced, and it is probable that the lines, or some of them, which cannot be ascribed to any known gases, may belong to the same gas as that giving the lines observed in the red. I append a table of some of these lines, which suggest possible coincidences in stellar and solar spectra; the numbers in brackets indicate the intensities of the lines, 6 being the maximum in the case of α Cygni, and 10 the maximum in the case of the eclipse spectrum.

Wave-lengths (Rowland).	Coincidences.
3961·4	α Cygni (6)
4035·2	Eclipse (2)
4058·6	,, (1)
4128·3	α Cygni (3)
4131·4	,, (3)
4224·0	Eclipse (1)
4255·7	,, (1)
4442·5	,, (3)

[1] *Roy. Soc. Proc.*, vol. lviii. p. 194.

In addition to the above lines there are others with which no celestial coincidences have been traced.

Some of the unknown lines at first noted in the red have been observed again in the gases obtained from other specimens; it is important to note that remarkable variations in the spectra have been observed in passing from one specimen to another.

Although the evidence in favour of a new gas is already very strong, no final verdict can be given until the spectra of all the known gases, including argon, have been photographed at atmospheric pressure and the lines tabulated. This part of the inquiry is well in hand.

November 28.—" Examination of Gases from certain Mineral Waters." By Alexander Kellas and Prof. William Ramsay, F.R.S.

A sample of gas of an inflammable nature from " Allhusen's Well," Middlesbrough, was tested for argon. The usual constituents, nitrogen, hydrocarbons, &c., were removed by the usual absorbents, magnesium, copper oxide, &c., and finally by sparking with oxygen over caustic soda. The spectrum of the residue was carefully compared with that of argon, and the lines were all found to be coincident. No new lines appeared, nor was any helium yellow visible. An incombustible gas from another well at the same place was also tested, and was found to contain 0·5 per cent of argon.

Some gas from a boiling spring near Reykjavik, Iceland, was found to contain a greater proportion of argon than is present in air, viz. 1·14 per cent. No helium could be detected in the gas, nor were there any lines which could not be recognised as belonging to argon.

" On the Percentage of Argon in atmospheric and in respired Air." By Alexander Kellas.

Experiments were made on the comparative amount of argon in ordinary air, and in air which had been frequently breathed, with the view of ascertaining whether, if the proportion of oxygen and carbon dioxide in air be very much altered, argon would either enter into, or be expelled from, the respiratory system. The experiments show that the proportion of argon to nitrogen remains nearly normal, even when the air has been greatly altered in composition by respiration.

From the experimental results it appears that 100 c.c. of nitrogen and argon of breathed air contains 1·210 c.c. of argon. This percentage is larger than that in normal air. One of two suppositions may be made: either the increased amount is due to the air having been confined over water during breathing, or argon is given off from blood in greater amount than it is absorbed, when the composition of the air in the lungs is so much altered; the former appears the more probable supposition. In any case the difference is not great; and it would appear that argon, like free nitrogen, plays no important part in the animal economy, save as a diluent.

Linnean Society, November 21.—Mr. J. G. Baker, F.R.S., Vice-President, in the chair.—His Grace the Duke of Bedford, Messrs. Bernard Arnold and E. B. Fernan were elected Fellows of the Society. Mr. B. B. Woodward was admitted.—The Rev. G. Henslow exhibited a MS. common-place book of the latter end of the fourteenth century. The entries in Latin and English were found to consist chiefly of medical recipes in which about 200 plants are named for their user, and some methods of distilling *Aquæ vitæ* described. In addition were some notes on geometry and astronomy, and calculations of altitudes and superficies. Mr. Baker thought the number of plants named at the date referred to was a matter of some interest to botanists, and suggested publication of the list of names with their identification where possible.—Mr. Henslow also exhibited a series of shells of *Buccinum undatum* and *Fusus antiquus*, showing the variation in form which occurs in the reparation of injury sustained at an early stage of life, the subsequently renewed whorls assuming shapes resembling those of other species in the same genus, and even in other and very different genera. Usually the uninjured whorls could be detected by the apex being of the normal character; but in some cases the abnormality appeared to be congenital, being carried completely into the ape. This raised the question whether these were acquired characters and hereditary, having been impressed upon the offspring born after the parent shell had been injured, and renewed by growth. Mr. E. R. Sykes and Mr. B. B. Woodward offered some criticism in the discussion which followed, and deprecated the suggestion of anything like " mimicry," the resemblances in question being regarded as purely accidental.—Mr. T. H. Buffham exhibited lantern slides of a red marine alga, *Bonnemaisonia hamifera*, Hariot, found floating in the sea at Falmouth. This species, recorded previously only from Japan, bears thickened branches terminating in a hook (hence the specific name), in this respect resembling *B. californica*, Buffham, which was also shown. Various microscopic characters of each were described and compared with those of *B. asparagoides*, Ag. It was suggested that if *B. hamifera* had been introduced from Japan, it could only have been from spores, or possibly the hamose branches might develop into plants, since the Falmouth specimens were quite fresh, and must have been living near the place of discovery.—Remarks on the mode of distribution of algæ were made by Mr. George Murray and Mr. E. A. Butters.—Dr. D. Morris, C.M.G., read a paper on the development of a single seed in the fruit of the cocoanut palm (*Cocos nucifera*). Alluding to the occurrence of palms with twin and trifid stems arising from one base, it was shown that these were due (1) to several seeds in one fruit; (2) to more than one embryo in a seed; or (3) to a branching of the primary shoot. In cases cited by Rumphius, Forbes and others, several seeds were found in one fruit. The course of the development of the single cell was illustrated by means of lantern slides. The obliteration of the two cells began about the second or third week after the spathe was open. By the end of the seventh week they were reduced to narrow slits, which were still traceable in the mature fruit.—On behalf of Mr. A. J. Ewart, Prof. Harvey Gibson gave an abstract of a paper on assimilatory inhibition, the causes by which it may be induced, and their influence on vitality. It was shown that most inhibitory agencies operate by inhibiting the initial stages in assimilation, but any cause affecting the rapidity of removal of carbohydrates from assimilatory cells will also affect their power of assimilation, the commencement of which is determined mainly by the development of the chlorophyll pigment, but is also influenced by other indeterminate factors probably plasmatic in origin. The paper dealt mainly with the discussion of experiments with a large number of plants, and criticism of the results arrived at by other investigators. An interesting discussion followed, in which Dr. Scott, Prof. Reynolds Green, and Prof. Weiss took part.—Mr. A. C. Seward gave the substance of a paper on a new species of *Pinites* from the Wealden (England).

The Institution of Civil Engineers, December 17.—Sir Benjamin Baker, K.C.M.G., President, in the chair.—The design and testing of centrifugal fans, by Mr. H. Heenan and Mr. W. Gilbert. The object of the experiments recorded in this paper was to determine the best form of fan-blade and fan-case, and the most economical diameter and speed of a fan, to produce any required volume of air at a given pressure. The comparative output of fans of the same type, but differing in size, showed that, if they were run at the same tip-speed and produced the same water-gauge, the air-discharge would be proportional to the centre section of the fan, that was, to the diameter multiplied by the width. A series of tests made to determine the efficiency of an expanding chimney was also described. Air was passed from a fan through a delivery tube into an expanding chimney, the sides of which could be set at any desired angle to the centre line of the tube. The efficiency for any angle was obtained by dividing the vacuum observed at the throat of the chimney, by the calculated vacuum due to the reduction of velocity of the air as it passed from the inlet to the outlet of the chimney. The results of the tests showed that the angle on each side might be as much as 15° without loss of efficiency. The air speed recommended at the chimney outlet was 20 feet per second, and the efficiency with this speed varied between 0·43 for 6° opening, and 0·42 for 15° opening on each side.

Mineralogical Society, November 19.—Anniversary meeting.—Prof. N. S. Maskelyne, F.R.S., in the chair.—The following officers and members of Council were elected: President, Prof. N. S. Maskelyne, F.R.S.; Vice-Presidents, Rev. S. Haughton, F.R.S., Dr. Hugo Müller, F.R.S.; Treasurer, Mr. F. W. Rudler; Foreign Secretary, Prof. J. W. Judd, F.R.S.; General Secretary, Mr. L. Fletcher, F.R.S.; ordinary members of Council, Prof. Green, F.R.S., Mr. Harker, Prof. Lewis, Mr. Pringle, Mr. Prior, Mr. Thomson, Mr. Tutton, Mr. Watts, Prof. J. Geikie, F.R.S., Mr. Hutchinson, Mr. Kitto, Lieut.-General C. A. McMahon. Mr. J. H. Collins was elected an auditor in place of Mr. F. Rutley, resigned. The Rev. Mark Fletcher and Mr. R. C. Webb were elected members of the Society.—Mr. Wm. Barlow read a paper on homogeneous structures and the symmetrical partitioning of them, and

exhibited models, manufactured by himself, to illustrate the manner in which various types of cubic symmetry can be constructed from units composed of any material distributed in the least symmetrical manner compatible with the requirements of that system. The models were hollow cubes, each containing three small hands affixed to one diagonal, right hands in some cubes and left hands in others. The author insisted upon the desirability of regarding the problem as one of the homogeneous distribution of matter without any limitation as to the form of the units, herein placing himself in opposition to the recently expressed views of Fedorow, who regards parallelohedra as the basis of all crystalline structures.—Prof. A. S. Herschel exhibited a number of intricate coloured models, made by himself, to illustrate the symmetrical partitioning of space, and indicated the various ways in which they may be viewed as interpenetrating or juxtaposed compartments. In the discussion which followed, Mr. Tutton agreed with Mr. Barlow's conclusion that the space-units should not necessarily be endowed with the same symmetry as the whole solid, and suggested an analogy between the author's conception of a growth of the hands whereby they might meet and fill the space with close-packed units, and the growth in volume which may occur when one metal in a salt is replaced by a heavier one of the same series. The President observed that such space-partitioning surfaces are purely imaginary; their form and dimensions must vary with temperature-changes, &c. The morphology of crystals has had nothing to learn from the geometry of crystal tactics; on the other hand, it has corrected and guided the course of those geometrical inquiries. The future working-out of the relations of stereo-chemistry to morphology and to actics will give significance to the stereohedra and parallelohedra of Fedorow, and will perhaps explain the existence of planes of symmetry, a principle which underlies any true theory of crystal-structure.

PARIS.

Academy of Sciences, December 16.—M. Marey in the chair.—On a theorem in geometry, by M. J. Bertrand,—The composition of flour and other products of roller milling. This is an attempt to place the operation of milling upon a scientific basis. The products of the fining were separately weighed and analysed, and samples of bread made from each.—Observations on Brooks' comet (1895, November 21) made at the Paris Observatory, by M. G. Bigourdan.—Observation of a meteor, by M. G. Bigourdan. A very brilliant meteor seen 7h. 4m. 50s. p.m., December 15. It appeared to be moving very nearly horizontally at a height of 45° in the direction from east to west.—A new explanation of the phenomenon of the solar prominences, by M. J. Fényi.—The equation to derived partials with constant coefficients, and on non-analytical functions, by M. E. Borel.—On the rolling of two surfaces on each other, by M. E. Cosserat.—Measurement of the force acting on a non-electrified dielectric, placed in an electric field, by M. H. Pellat. An experimental proof of a theorem established in a previous note.—The direct combination of nitrogen with metals, by M. A. Rossel. It has been found that if an intimate mixture of finely-powdered calcium carbide with magnesium powder is heated with free access of air, the metal is almost completely transformed into the nitride. Finely divided aluminium, zinc, iron, and copper act similarly.—On the preparation and properties of crystallised chromous sulphide, by M. A. Mourlot. Metallic chromium was heated to a high temperature in a stream of sulphuretted hydrogen. The product proved to be the protosulphide, which on strongly heating was obtained in the crystalline state. A study of its behaviour towards a number of reagents showed that it is a compound of considerable stability.—On lithium subchloride, by M. Guntz. This is prepared by heating lithium and the ordinary chloride together to a red heat. The product decomposes water with the liberation of hydrogen.—On some new saffranines, by M. G. F. Jaubert.—Study on *Aspergillus orizæ*, by M. E. Sorel. It is shown that if cultures of the conidia in malt-wort are subjected to certain temperatures, and in presence of hydrofluoric acid, the mycelium first produced breaks down into a yeast-like form capable of isolation by repeated cultivation in malt-wort. This yeast is active, and whilst fermenting an ordinary malt solution produces no mycelium. The latter, however, can be reproduced again under special conditions, thus completing the life cycle.—Functional assimilation, by M. F. Le Dantec.—On the process of development in the Filigranes and Salmacynes, by M. A. Malaquin.—On the influence of electricity on the development of the embryo of the chicken, by M. C. Dareste.—Study of the effect of the colour of light upon vegetation, by M. C. Flammarion.—On some vegetable impressions in the coal-measures of Southern Brazil, by M. R. Zeiller.—A new disease in the leaves of the larch, by M. E. Mer.

NEW SOUTH WALES.

Linnean Society, October 30.—Mr. Henry Deane, President, in the chair.—On the occurrence of diatomaceous earth at the Warrumbungle Mountains, N.S.W., by Prof. T. W. Edgeworth David.—Jottings from the Biological Laboratory, Sydney University, No. 18.—On certain points in the structure of the pearly nautilus, by Prof. W. A. Haswell.—The grey gum of the North Coast districts (*Eucalyptus propinqua*, sp. nov.), by Henry Deane and J. H. Maiden. This grey gum has for many years held an uncertain botanical position, having been ranked, at different times, by botanists under *E. punctata*, *E. saligna*, and even *E. viminalis*. The authors believed that it but perpetuates the confusion to place it under any existing species. Its bark and timber considerably resemble those of *E. punctata*. From this species *E. propinqua* differs in the smaller size of the flower-buds and fruits; and in the narrow lanceolate leaves which also have more parallel and less prominent lateral veins than *E. punctata*. The calyx-tube and also the operculum of *E. propinqua* are more distinctly hemispherical, and its flowers more pedicellate. The fruit of *E. punctata*, though variable in size, is always larger and more cylindrical than that of *E. propinqua*. *E. propinqua* was fully described, and its affinities and differences from other species were further given in some detail. The species is found from the Hawkesbury River to the Tweed River, and probably will be found to extend to South Queensland.—On new localities for *Peripatus*, by Edgar R. Waite.

THURSDAY, JANUARY 2, 1896.

THE ALPS FROM END TO END.

The Alps from End to End. By Sir William Martin Conway. With 100 full-page illustrations by A. D. M'Cormick. Pp. xii + 397. (Westminster: Constable and Co., 1895.)

SIR WILLIAM CONWAY has given us in this new work a racy account of a three months' summer journey through the Alps from west to east. To a climber of Himalayan fame it was not much that the "Playground of Europe" had to offer in the way of enterprise or difficulty. Neither was it Sir William Conway's intention to combine scientific aims with his mountaineering feats in the Alps, as he had done in the Himalayas. The purpose he had in view was

"to devise a route . . . so that a climber might begin at one extremity of the snowy range, and walk up and down through its midst to the other extremity over a continuous series of peaks and passes" (p. 3).

The tour began at Turin, on June 1, 1894, and ended on August 26, at Gastein. Seven were of the party—Sir William Conway and Mr. E. A. FitzGerald, accompanied by three well-known "high tour" guides, Carrel, Zurbriggen, Aymonod, and two Gurkhas, Amar Sing and Karbir, who had been with Sir William Conway in his Himalayan journeys.

The first part of the route lay along the French-Italian frontier, traversing the Maritime, Cottian, and Graian Alps. The climbs here were not so successful as they might have been, owing to late snow on the mountains, general bad weather, and the occasional interference of the frontier gendarmerie. The narrative gives many amusing accounts of custom-house colloquies. We read of the "inquisitive Jack-in-office" and "suspicious lieutenants," and we sympathise with the would-be climbers waiting hours at Colle di Tenda for a colonel "who was either asleep or out," and at last sent a "ghostly captain" to assure the party of his distinguished consideration, but to announce that *this fortified circle of the hills was closed to all the world!* The author's keen sense of humour is seen to full advantage in those early chapters.

The first successful climb was that of Pelvo d'Elva, on June 8, followed on June 12 by the ascent of Monte Viso, both in the Cottian Alps. The cold must have been very intense.

"Some cold cream in FitzGerald's pocket was turned into a stony lump. Our knitted gloves were as stiff as boards. Icicles hung in rattling plenty from beards and moustachios . . . . " (p. 53).

Unfriendly weather pursued them into the Graian Alps, but on June 22 the Aig. de la Grande Sassière was climbed under favourable skies, and a glorious panorama rewarded them. They could see from the Maritimes in the south to Mont Blanc and the Swiss giants in the north. The photograph of the Sassière peak is a good representation of the broad slabs of slaty rock so characteristic of this region of the western Alps.

Very pleasantly written pages relate the journey from the Graians into the *Valais*, over the Col de St. Grat and down the Ruitor glacier to La Thuille. Sir William Conway writes:

"Assuredly nowhere else is Mont Blanc better seen than from this Ruitor névé. No foreground more admirably serves to set off its blue shadowing buttresses and cream-coloured domes than the flat white area of this magnificent snow-field" (p. 94).

The party was now in full training, and the glaciers and peaks of the Mont Blanc massif were attacked with extraordinary vigour. The reader is hurried through the grand natural gateway of Courmayeur, torn along the lovely Allée Blanche—where he is allowed to hear nothing but Aymonod's chatter, and to see little except two cowherds fighting and a background of glacier—then, after rapid climbing up the Miage glacier, he is given time for reflection in the Dôme Club-hut. The next day, too, when the summit is reached, the reader cannot but be disappointed that Sir William Conway so summarily dismisses the expected description of the view. Any one who has read Mr. Leslie Stephen's "Sunset on Mont Blanc," will feel the wide difference between the essayist who faces the difficulties of Mont Blanc because he is first and foremost a lover of nature, and the author who is steeped in professional climbing, and includes Mont Blanc in a record tour! We are glad that the continuation of the route was made over Col d'Emaney and the Salanfe Alp, for this region deserves to be better known amongst English travellers.

The most effectively written chapters in the book are those which follow, on the "Western Bernese Oberland." There the author strikes many wise notes of experience. For instance:

"All high mountains command fine views, but there are differences between them, both in kind and degree. I hold that on one side at least there should be green and fertile land. If a lake is visible, so much the better. The eye, too, should somewhere plunge into a profound valley. The great ranges should not spread themselves out like a procession, but should be grouped into masses. The Diablerets' view conforms to all those conditions" (p. 138).

Every one knows how the pleasant châlet-life helps to enhance and soften the scenery of the mountain pasturages between Lake Geneva and Lake Thun. Sir Willam Conway treats this part charmingly, and, thanks to the garrulous guide Aymonod, he acquaints the reader with many secrets of Swiss cheese-making.

A much sterner aspect of Swiss experience is presented in the chapter on Monte Rosa. The ascent was undertaken on this occasion by Sir William Conway entirely for the sake of the "reading public." A fearful gale blew on the mountain, and we question if charitable England will agree that the amount of enlightenment gained entirely justified the foolhardiness of the party of climbers and the frost-bitten toes of Amar Sing! The author writes in his enthusiasm:

"Such struggles with nature produce a moral invigoration of enduring value . . . They bring a man in contact with cold, stony reality, and call forth all that is best in his nature. They act as moral tonics. Of all the time I have spent in the mountains, such days as these have possessed upon the whole the most enduring value" (p. 174).

There is an unmistakable Cromwellian spirit about this.

The description of the journey through the eastern Bernese Oberland is inclined to be scrappy. It is here that the words "couloir" and "bergschrund" are explained for the first time in the book, although they have been in constant use by the author in the preceding 200 pages. Such flaws of orderly treatment frequently occur, and remind us that the narrative was originally written for a serial journal. The Alps of Uri and Glarus repeat the more pastoral scenes of the western Oberland, but the inhabitants are less kindly criticised.

The Austrian frontier was reached on August 1. The chief peaks ascended in Austria were the Scesa Plana in the Rhaetikon, the Weisskogl in the Oetzthal Mountains, the Hochpfeiler in the Zillerthal Mountains, the Gross Venediger, the Gross Glockner, the Klein Glockner, and the Ankogl Mountain. During the latter part of the journey, east of the Brenner Pass, Sir William Conway was accompanied only by the two Gurkhas. The departure of the others, especially the loss of Aymonod's talk, was not without its effect on the "Journal." Side-incident distributed itself around fellow-travellers, and the German and Austrian Club-huts received a large share of attention at the author's hands.

Taken as a whole, the "Alps from End to End" is a notable example of the fact that occasional papers published in a "serial" seldom cohere satisfactorily into an independent volume. As a literary production, the book is not likely to add to the author's fame. It is one which will live only in the form of extracts. Fine descriptive passages occur in plenty, but they are loosely padded together. Ideas are fragmentary, and repetitions tiresome. The state of the weather and the digestion of the party play naturally enough a most important part in a faithful journal of Alpine climbing, and if the journal be read by weekly instalments, those items may act pleasantly as a foil to the main interest of climbing. But it will try the patience of most readers to go through the variations of this theme, chapter after chapter, in a one-volume book. Still, the book contains a mass of useful hints and information for ardent Alpine climbers. The author conveniently condenses the details of each part of the route, and gives the time record, at the beginning of each chapter. These small summaries are admirable storehouses of reference for the practical walking tourist.

Every one, tourist or stay-at-home, will feel bound to admire the *sangfroid*, pluck, and determination which carried the author through an extremely difficult programme of climbs in all weathers. But the Alpine devotee will regret the business-like way in which the tour was accomplished, as well as the unsympathetic attitude often shown by the author towards the hard-wrought inhabitants of these high regions. Sir William Conway is at his best when he discusses views, peaks, cloudland, and the elements constituting a good panorama. Nothing could be neater, for example, than the following aphorism: "That panorama is the most perfect which the eye follows round with the greatest luxury of movement" (p. 348).

There is one feature in the book which cannot entirely be passed over. It is the author's touch of impatience with the familiar figure in the Tyrol—the German "Rücksack" tourist who carries his belongings on his back, and is his own guide. The same feeling is extended to many of the well-meant efforts of the German and Austrian Alpine Club for the aid and better enjoyment of such tourists.

"The Tirol is cursed with wire-ropes. Wherever a good scramble was offered by nature, it has been ruined in this fashion by man, with the result that any bumpkin can get conveyed almost anywhere in this mountain area" (p. 275).

Sir William Conway seems to forget what an enormous saving it is for hundreds of the less wealthy tourists to be able to climb mountains and cross cols safely without paying the tax levied by the guides. And that is what the step-cutting and path-making of the German and Austrian Club have made possible in their Alpine territory. On the other hand, an economical tour in the *Valais* is almost impossible. Care seems to be taken by the people there not to put up a single signboard for the guidance of the walking tourist! This certainly leaves nature's beauty unimpaired; but we fear it is the commercial instinct, and not the love of beauty, which rules the Swiss.

Little can be said of the numerous illustrations contributed by Mr. A. D. M'Cormick to Sir William Conway's book. They are drawn from photographs; but, although interesting, they lack the artistic freedom and cleverness which made the charm of Mr. M'Cormick's original sketches for "Climbing in the Himalayas."

THE ARCHEGONIATE SERIES OF CRYPTOGAMS.

The Structure and Development of the Mosses and Ferns. By Douglas Houghton Campbell, Ph.D., Professor of Botany in the Leland Stanford Junior University. Pp. vi + 544. (London: Macmillan and Co., 1895.)

BOTANISTS have been waiting with considerable expectation for the appearance of Prof. Campbell's book on the Archegoniate Series of Cryptogams. Neither the mosses nor the ferns and their allies have been comprehensively treated for some years, and thus, whilst much individual work has been accomplished in this department within recent times, it has become exceedingly difficult for those whose special interests happen to lie in other directions, to keep abreast of the ever-flowing tide of information respecting these most important families of plants.

Thus, had Dr. Campbell merely given us a text-book, in the sense in which that word is too often used—or misused—his claims to the gratitude of the morphologist might have been by no means inconsiderable. But in reality his treatise can scarcely be termed, with propriety, a text-book; and herein lies at once its strong and, we may venture also to add, its weak points. It is the outcome of a very extensive series of researches on the development and structure of the plants denoted as archegoniate cryptogams; and there is a peculiar freshness in the treatment, which can only be attained as the result of personal and intimate knowledge of the objects under discussion. This quality at once raises it far above the level of the ordinary book, in which the character of the compiler is often but too painfully apparent.

A very noticeable feature of the volume is the large space devoted to the consideration of the Liverworts. It is quite surprising how little attention botanists have been accustomed to pay to this group; many are quite content with acquiring a knowledge of *Marchantia*, which, as it happens, is a very specialised form, and not in the least degree typical of Liverworts taken as a whole. This neglect becomes the less intelligible when one considers the extreme diversity of outward form exhibited even within the limits of a single genus, a diversity only perhaps paralleled by some genera of lichens, or of algæ. And again, their position at the base of the archegoniate series should have sufficed to rescue them from a condition of such unmerited oblivion. Thus the author has done good service by devoting 140 pages to the Hepaticæ alone. It is, perhaps, to be regretted that he did not lay more emphasis on the extent of morphological specialisation which may be observed amongst the species of individual genera; thus, for example, all gradations may be traced in forms included in *Symphyogyna*, from a creeping flat thallus to a complicated branch system, recalling that of the sporophyte of many Hymenophyllaceæ. No doubt this would have entailed an increased number of pages, but, we think, the addition would have been very welcome.

We notice one or two slips here and there. Thus it is stated on page 97 that all the acrogynous Jungermanniaceæ possess a three-sided apical cell, whereas at least one species of *Physiotium* is known in which the cell is lenticular in transverse section. But these are but trivial errors, and the general summing-up of the Hepaticæ strikes us as extremely good, even though we may hesitate before accepting all the author's conclusions.

The Vascular Cryptogams are treated very fully, as one would have expected from a writer who has himself contributed so much to our knowledge of the group. But occasionally, if we may venture to say so, the investigator is perhaps a little too much to the front; and whilst individual plants are fully described, and very complete and minute accounts are given of the development of their various organs, one loses, to some extent, the feeling of a wide synthetic grasp of the plants as a whole. It is true, however, that this is atoned for by the suggestive summaries and discussions on phylogeny at the end of the chapters.

Many readers will probably wish that Prof. Campbell had devoted a little more space to a comparative treatment of the external forms, and had also given some account of the numerous biological adaptations which are so abundantly exhibited by many ferns and mosses; and we cannot help feeling that this would have been acceptable, even if it had necessitated the sacrifice of space now devoted to details of development.

The only point about the book which really strikes us unfavourably is the scanty recognition accorded to Palæontology. It is just amongst the vascular cryptogams that the palæophytologist is at his best, and we venture to express the hope that in future editions this most important branch of the subject may be far more fully treated.

If we have seemed to have indulged in a few adverse criticisms, this has not been done with any hostile intention, but merely by way of attempting to point out how, in our judgment, a really fine work may perhaps be improved. Enough, however, has, at any rate, been said to show that Prof. Campbell has rendered a most important contribution to the literature of botany; and we cannot, finally, suppress an expression of gratification that it should have appeared in the English language.

OUR BOOK SHELF.

A Laboratory Manual of Organic Chemistry. By Dr. Lassar-Cohn. Translated by Alexander Smith, B.Sc., Ph.D. Pp. vii + 403. (London: Macmillan and Co., 1895.)

IT will be readily understood in these days of rapid research that the appearance of a compendium of the latest reagents, processes and apparatus, intended to curtail the labour of the laboratory, would prove acceptable to organic chemists, and it is not surprising that the second German edition of this work should have appeared within a brief period. Its success in Germany may be taken as a guarantee that the English translation will be well received. The original will already have found its way, without doubt, into some of our laboratories. There are many useful laboratory methods scattered through the literature, which are frequently difficult to lay one's hand on at once. The present volume, which has been compiled with much discrimination, gives an account of all the important laboratory operations used in organic research, carefully described and illustrated. In these descriptions either the original account is reproduced, or a sufficiently detailed description is supplied by the author, so that a final appeal to the reference may generally be dispensed with—an important point, since herein lies the essence of the book's utility. The less important methods are briefly mentioned with a reference to the original paper. To try and strike a mean between these two extremes is obviously useless, and occasionally the author falls into this error. For example, under "aluminium chloride" (p. 105), it is stated that this substance is prepared from aluminium and chlorine. Then follows a fairly long account of a method by Gattermann, from aluminium and hydrochloric acid. The description is unaccompanied by any diagram, and is so incomplete that I am confident that any one who attempted to prepare it for the first time from this description would fail. In such a case the author would render a greater service by simply giving the reference.

The book does not aim at teaching the principles of organic chemistry, and it is perhaps not fair to find fault with some of the expressions and definitions used, which are apart from its main purpose. One brief reference may be permitted.

Chapter xii. (p. 10) contains a general account of "condensation." The writer has never met with any good definition of this term, and it is perhaps, as Gmelin said of the relation of organic to inorganic chemistry, more easily felt than defined; but surely we have here a needless confusion of ideas or, at least, of language. In the first paragraph we read: "By condensation we mean the formation of a substance from two others with loss of water, alcohol, hydrochloric acid, ammonia, or a halogen from both components." That the *two others* are not necessarily organic substances we learn from the next paragraph, where an example of condensation is given in the case of hydroxylamine and an aldehyde. Consequently we may include in this term the formation of ethereal salts, nitro-compounds, sulphonic acids, &c. Further down we read: "We include under this heading also the phenomenon of internal condensation, in which a body loses water and forms a new substance." Is the formation of ethylene from alcohol *condensation?* In the next para-

graph we are told that loss of water is not essential; but that polymerisation is a form of condensation. In the next we read: "By means of condensation (*i.e.* the formation of a substance from two others) chemists have been able to prepare far more new bodies and entire classes of bodies than by any other process."

With the exception of a few mistakes in spelling, especially of proper names, and a few omissions in the index, the work of the translator leaves nothing to be desired.

J. B. COHEN.

Physikalisch-chemische Propaedeutik, Erste Hälfte. Von H. Griesbach. (Leipzig: Wilhelm Engelmann, 1895.)

THIS work is designed mainly for the use of the chemist and the doctor; for, according to its author, the former, when engaged on certain legal inquiries or on questions relating to hygiene, must know something of medical science, and the latter, in order to follow his calling to advantage, must be familiar with much that is chemical and physical.

The present volume is the first half of the work, and deals with physico-chemical science and logic, the origin, nature, methods, and aim of physico-chemical science, measurement and systems of measurement, time, space, matter, energy, motion, velocity, the divisibility and constitution of matter, hypotheses regarding the ether, the atomic hypothesis, living and dead matter, organised matter as producing fermentation and disease, &c.

The reader requires no special scientific knowledge to follow the information supplied, which differs essentially from that given by most of the text-books, as a detailed historical account, containing short biographical sketches of leading investigators, is given in the case of each of the subjects dealt with. References are also given to original papers, and although the material discussed is mainly theoretical, apparatus and methods are also treated to some extent.

For a book which deals with subjects so widely apart as, say, the genesis of the elements and the karyokinesis of a living cell, the information is remarkably accurate, up to date, and well arranged; and the historical method adopted in the case of subjects which are but seldom handled in this way, makes the book specially interesting and valuable.

J. W. R.

The Pterophorina of Britain. By J. W. Tutt, F.E.S. Pp. 161. (Hartlepool: John E. Robson.)

ALTHOUGH dignified with the title of a monograph, this work, reprinted from the *British Naturalist*, is a carelessly compiled reproduction of almost every statement which has ever been published upon the British species of Plume-moths. Mr. Tutt has not attempted to condense into a useful or readable form this mass of crude material, which, however, may prove attractive to a certain type of collector. The generic diagnoses, unaccompanied by synoptic tables or figures, are taken mainly from Jordan's abstract of Wallengren's "Scandinaviens Fjädermott," and the specific characters are given mostly in the words of other writers, two or three descriptions being sometimes quoted for a single species. The book is roughly printed, and contains several misspellings of names; it will bring little credit to author or publisher, though as a compilation it may prove useful to those who care to search its pages.

Submarine Telegraphy and other papers. By James Bell, A.Inst.E.E., and S. Wilson. Pp. 63. (London: *Electricity* Office, 1895.)

A COLLECTION of papers, originally published in the columns of *Electricity*, dealing with matters belonging to technical telegraphy. Will be especially serviceable to persons engaged in the postal telegraph service, but appeals to all practical electricians.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Astronomical Theory of the Glacial Period.

TWO letters have recently appeared in NATURE (October 17, p. 594, and November 29, 1895, p. 29), in which Sir Henry Howorth attacks Sir Robert Ball as the author of a work entitled "The Ice Age," on the ground that the supposed astronomical cause of glaciation is totally inadequate to produce the alleged effect.

I do not now write because I have any new contribution to make to the discussion, but because the author of the review in NATURE (January 28, 1892) of "The Ice Age" might perhaps be expected to express an opinion on the subject in the columns of NATURE.

I still think that the book has the merit of laying down the simpler issue as to the direct effect of the variation in the eccentricity of the earth's orbit on climate, and of setting aside the many collateral causes with which Croll has somewhat clouded the subject.

I wish, however, to reiterate that Sir Robert Ball has, as I think, emphasised the wrong numbers, when he lays so much stress on the ratio 63 to 37, which expresses the ratio of the heat received by a whole hemisphere in its summer to that received in its winter. The really important point to consider is what change that ratio undergoes when the eccentricity of the orbit varies.

In my review it was shown that, with maximum eccentricity of the earth's orbit, and with summer in perihelion, the ratio of the daily supply of heat in summer to that in winter must be augmented by the factor $\frac{199}{166}$; whilst with summer in aphelion the same ratio must be reduced by the factor $\frac{166}{199}$. Thus the contrast between the two configurations is best represented by the ratio of 199^2 to 166^2, or of nearly 6^2 to 5^2, or say as 3 to 2. These are the numbers which deserve emphasis.

The astronomical theory has, however, been recently subjected to a powerful criticism by Mr. Culverwell in some papers in the *Geological* and *Philosophical Magazines*,[1] and the criticism is, I understand, adopted by Sir Henry Howorth. A concrete case (using only round numbers) will express very shortly Mr. Culverwell's argument. At present, with practically zero eccentricity of the earth's orbit, in latitude 51° the ratio of the daily supply of heat in summer to that in winter has a certain magnitude, say A. Then the corresponding ratio for latitude 55° is $\frac{5}{6}$ A; and for latitude 47° is $\frac{6}{5}$ A. Now this difference is found to have nearly the same value, viz. 4°, for all the middle latitudes, so that it may be concluded that the alleged cause for glaciation would give London a climate something like that of Yorkshire; and the converse would produce a climate something like that of mid-France. The parallelism of the two cases is by no means perfect; but with allowance of the widest margin of uncertainty, it seems that neither a polar nor a tropical climate could be produced by the astronomical cause.

Is there any great flaw in Mr. Culverwell's argument? I do not at present see one; and great as are the uncertainties of the case, they seem insignificant as compared with those involved in calculations founded on the temperature of space, as used by Croll and Ball. Mr. Culverwell has independently carried to its logical conclusion the same line of argument as that of my review, and I can now only confess with regret that I did not perceive whither it tended.

The astronomical theory of the great changes of climate of which geology affords evidence is so alluring, that I cannot sur-

1 *Phil. Mag.*, December 1894, p. 541; *Geolog. Mag.*, decade iv. vol. ii. No. 367, p. 3, January 1895, and No. 368, p. 55, February 1895. Since this letter has been in type, I have read a valuable paper by Mr. G. F. Becker (*Amer. Journ. Sci.*, vol. xlviii. August 1894), in which he concludes that zero eccentricity of the earth's orbit will present the condition most favourable to glaciation. I have to thank Sir H. Howorth for reminding me of this paper.

render it without regret, and should gladly welcome a destructive criticism of Mr. Culverwell's argument.

I have had some conversation with Sir Robert Ball on this subject, and I find that he is not as yet disposed to change his opinion. He contends that, when we bear in mind that it is in the tropics that the great oceanic currents get their warmth, we should admit that the change in the daily supply of heat by one-fifth part is competent to produce a great change in northern climates. Whilst I think that he would not now lay much stress on the quantitative results derived from the supposed temperature of space, he would still maintain that the cause is adequate to the effect. But does not this bring us nearly back to Croll's point of view, and demand a discussion of the effect of diminished or increased sun-heat on oceanic circulation?

December 16, 1895. G. H. DARWIN.

[At the request of the Editor, one sentence has been erased from the original letter.]

Barisal Guns.

WITH reference to Prof. Darwin's letter in NATURE of October 31, 1895, relative to Barisal Guns, I enclose a communication, which I received from an observer familiar with the phenomenon.

Medical College, Lahore. D. G. F. GRANT.

I first heard the Barisal Guns in December 1871, on my way to Assam from Calcutta through the Sunderbans. The weather was clear and calm, no sign of any storms. All day the noises on board the steamer prevented other sounds from being heard; but when all was silent at night, and we were moored in one or other of the narrow channels in the neighbourhood of Barisal, Morelgunge and upwards, far from any villages or other habitations, with miles and miles of long grass jungle on every side, the only sounds the lap of the water or the splash of earth, falling into the water along the banks, then at intervals, irregularly, would be heard the dull muffled boom as of distant cannon. Sometimes a single report, at others two, three, or more in succession; never near, always distant, but not always equally distant. Sometimes the reports would resemble cannon from two rather widely separated opposing forces, at others from different directions but apparently always from the southward, that is seaward. We were not very far from the sea when I first heard them, and on mentioning to an old lady on board that I heard distant cannon, she first told me of the mysterious sounds known as the "Barisal Guns." For the next two years I was in Upper Assam, above Goalpara, and do not remember ever hearing them there; but in 1874 I was working in the Goalpara district in the tract south of Dhubri, between the Brahmaputra and the Garo Hills; sometimes near the river, sometimes near the foot of the hills, at others between the two. I gradually worked down as far as Chilmari Ghât (I think it is called), the landing-place for Tura, the headquarters of the Garo Hills district, and distant quite 300 miles from the mouths of the Brahmaputra and Ganges. The villages are few and far between and very small, firearms were scarce, and certainly there were no cannon in the neighbourhood, and fireworks were not known to the people. I think I am right in saying I heard the reports every night while south of Dhubri, and often during the day. The weather on the whole was fine. Short, sharp "nor'westers" occasionally burst on us of an evening, with much thunder and lightning; but the days were clear, and, as a rule, the sounds were heard more distinctly on clear days and nights.

I specially remember spending a quiet Sunday, in the month of May, with a friend at Chilmari, near the river-bank. We had both remarked the reports the night before and when near the hills previously. About 10 a.m. in the day, weather clear and calm, we were walking quietly up and down near the river-bank, discussing the sounds, when we heard the booming distinctly, about as loud as heavy cannon would sound on a quiet day about ten miles off, down the river. Shortly after we heard a heavy boom very much nearer, still south. Suddenly we heard two quick successive reports, more like horse-pistol or musket (not rifle) shots close by. I thought they sounded in the air about 150 yards due west of us over the water. My friend thought they sounded north of us. We ran to the bank, and asked our boatmen, moored below, if they heard them, and if so in what direction. They pointed south!

As we often did with boatmen, we asked these their opinion of the sounds. They said they heard them at all seasons and in every direction all up the river from Serajgunge to Dhubri—their beat; that they were in the air, and came from the gods (Deota) celebrating the continuous marriage of the Ganges (the goddess Ganga) with the Brahmaputra (son of Brahma); that they were heard in their fathers' time, and long before. We could elicit nothing further from them or others.

The year previous I had discussed the sounds with Captain Stewart, of the Survey of India Department, who had some years previously been employed on the Survey of the Sunderbans tracts. He said the reports were heard all over the Sunderbans; that several experts had failed to account for them. He once had a theory that they were caused by submarine eruptions in the Bay of Bengal; but this would hardly account for them 300 miles distant, and I believe they are never heard out at sea in the bay.

I have heard planters (who have heard them near the hills where bamboo jungles abound) say that they were merely reports caused by bamboos bursting in jungle fires. But they are heard far from all bamboo jungles, and in the absence of jungle fires.

Strange to say, I next heard the reports when crossing the Mahanadi River, between Purnea and Kishengunge in the old road from Sahebgunge to Darjeeling.

The time was about ten at night, the evening close, hot, and very cloudy, but no thunder anywhere. The booming sounded some miles away. There are no cannon anywhere in the neighbourhood, nor any large cities where possibly fireworks might be in progress. The year after I heard them again at the same place; on this occasion the sky was clear and starry, the time between 3 and 4 a.m., the booming distant but very distinct.

I have no theory. I fancy the sounds must be purely electric, but certainly have nothing to do with clouds, nor with cannon, nor fireworks, nor jungle fires.

If I can answer any other questions on the subject, I will be pleased to do so; but I think I have told you all I know.

G. B. SCOTT.

Remarkable Sounds.

I HAVE this day received from the Rev. W. S. Smith, Congational Minister of Antrim, Ireland, the following account of natural sounds connected in some way with Lough Neagh. The details are so interesting that I send them as a contribution to your present correspondence on natural sounds.

Highgate, N., December 19, 1895. C. TOMLINSON.

Lough Neagh is a sheet of water covering an area of upwards of 150 square miles, with very gradually receding shores, excepting at one or two spots. For many years after my settlement as minister here from England, I heard at intervals, when near the lake, cannon-like sounds; but not being acquainted with the geography of the distant shores, or the location of towns, or possible employments carried on, I passively concluded that the reports proceeded from quarrying operations, or, on fine summer days, from festive gatherings in Co. Derry, or Co. Tyrone. In time I came to understand that it was not from the opposite shores, but from the lake itself that the sounds proceeded. After questioning many of the local residents, I extended my inquiries to the fishermen, but they could assign no cause. A strange thing about the matter is that the people generally knew nothing of the phenomenon, and that it is shrouded in mystery. I have heard the sounds during the whole year. . . . I have heard the reports probably twenty times during the present year, the last being on a Sunday afternoon a month since, when I heard two explosions; but with two exceptions they have all seemed to come from many miles away, from different directions at different times. They have come apparently from Toome Bay, from the middle of the lake, and from Langford Lodge Point, about nine miles distant. A fisherman thought they must be the result of confined air that reached the lake by means of springs that are believed to rise here and there in the bottom. But the lake is shallow, seldom more than 45 feet deep. The depression now covered by the lake having been caused, it is believed, by volcanic action when the trap-rock of Co. Antrim was erupted, there may possibly be subterranean passages, though I confess their occurrence does not seem very probable; while the sounds emanate, as stated, from various parts of the lake. I have as yet spoken to no one who observed any movement of the waters when explosions took place, nor have I spoken to any one who was close to the spot at the time. Rather every one seems to have heard them only in the distance, which is strange, as fishermen are on the lake during many months in the year, at all hours of the day and night.

Last winter the whole of the lake was frozen over, for the first time since 1814. One fine afternoon, when the air was still, I was skating in the neighbourhood of Shande's Castle, when these mystical guns boomed forth their reports every five or six minutes. On the last day of the skating, when thousands of people from Belfast and elsewhere were assembled in Antrim Bay, there were two fearful boomings, that startled every one near me. They seemed to think some dreadful catastrophe had occurred, as the sounds appeared to proceed from not more than half a mile away. I never before heard them so near. The ice in Antrim Bay remained as it was, but I afterwards learned that it was then breaking up six miles away, but with no alarming sounds. Last February, when the ice of Lough Neagh was breaking up, a strange occurrence took place at Ardmore. A great ridge of ice, a mile and a half long, and 10 feet high, and 15 feet at the base, was formed along the shore during three days. There was a dead calm at the time, so that the ice was not thrown up by the waves. The ice along this part of the shore, for a third of a mile out, was intact; the ridge must have consisted of ice brought from a considerable distance, and forced under the shore ice, which was raised every few yards into small archways, and then shot out from beneath to the height previously specified. The pieces of ice were from half a yard square to bits of an ounce in weight, all mingled in the huge mass. Such a sight had not occurred since 1814, when, as I learned from a member of my congregation, who had seen it in that year, the water of the lake could not be seen from the shore-road on account of this icy obstacle. There are currents in Lough Neagh, but I am not aware of any strong enough to produce such an effect. W. S. SMITH.

Postcript.—In my former letter, an extract was given from Major Head's work, published some fifty years ago, and on again referring to it, I find the following passage:—"The cold increased to a very low temperature, the effect of which upon the extended sheet of ice that covered the bay, was remarkable. It cracked and split from one end to the other with a noise that might have been mistaken for distant artillery." This explains the sound to some extent in winter, but Mr. Smith says that the cannon-like sounds may be heard at any time of the year. This requires explanation. C. T.

IN your issue of November 14 last, Prof. McKenny Hughes appears to favour the idea that the curious sounds heard near the shores of Morecambe Bay, are due to the waves breaking "on the long, flat shore" thereof. I heard these sounds on Saturday, December 21, and could trace them to blasting operations near Carnforth. I heard them between 9.15 and 9.30 a.m., and the *tide was quite out*. So the "very suggestive coincidence" between the Bays of Bengal and Morecambe loses point! Further, it is seldom that the waves break at all, or even "curl over" on the shores of Morecambe Bay, where it is flat; but the water simply overflows the banks of the channel of the river Kent, whose course is followed by the tidal wave. There are limestone quarries at or near Arnside, Silverdale, Warton, Carnforth and Borwick. O. FIRTH.

Hawthorn House, Baildon, Yorks.

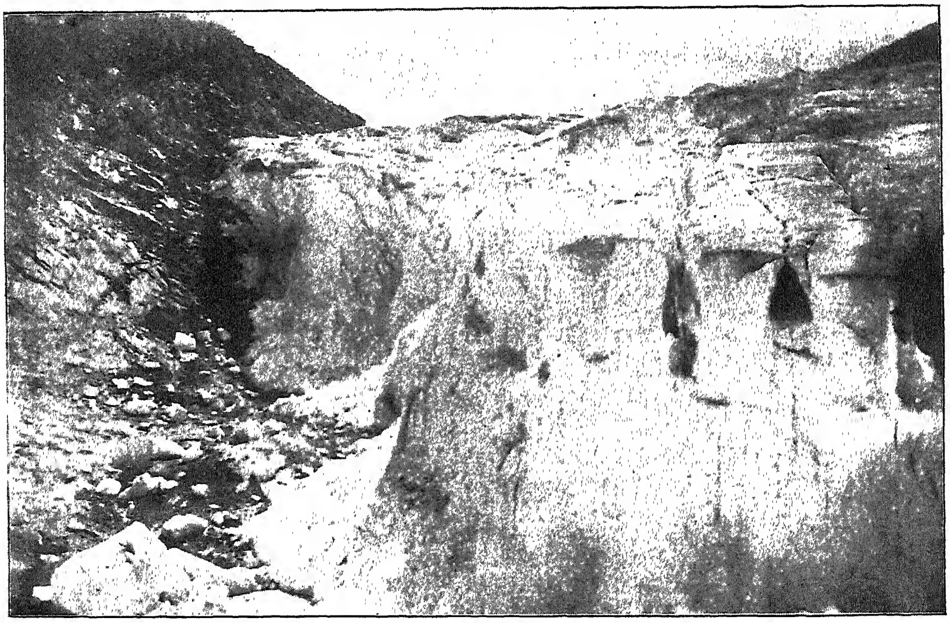
CHARLES DARWIN, in his "Naturalist's Voyage round the World" (new edition, 1890, p. 346), describes some curious earth-sounds heard in Northern Chile; he also gives references to Seetzen and Ehrenberg as authorities for the occurrence of similar sounds on Mount Sinai, near the Red Sea.

It is stated that the phenomenon is caused by sand in motion. WILLIAM STONEY.

Civil Service Club, Capetown, December 4, 1895.

The Merjelen Lake.

THE annexed illustration is reproduced from a photograph taken by me on August 16, 1890, when the lake was empty. How long it had been so, or how long it continued, I cannot say. So far as my memory serves me, there was no water whatever in it, and I distinctly recollect noticing the icebergs lying



high and dry on the bottom. I walked along what had been the margin of the lake on my way to the Aletsch glacier, which I ascended to the Concordia Hut. I hope the photograph may be of interest to Dr. Preller, and others who know the lake. GREENWOOD PIM.

Co. Dublin, December 19, 1895.

The Metric System.

I NOTE a call from Mr. John W. Evans, in NATURE for December 5, 1895, for the use of the metric system in meteorology. If this means the substitution of the metre for the yard, there can be no serious objection except this. In meteorological studies ·01" of air pressure is an extremely convenient limit, and in most inquiries only two figures are needed. On the other hand a millimetre (·04 inch) is altogether too large a limit, and one-tenth m.m. is too small. The labour of writing, averaging, and studying with the metric scale will be at least one-third greater than with the common inch scale to the same degree of accuracy. It is a very great pity that the French, in looking

for a convenient length to divide into a thousand parts, did not take up the already existing yard, which is nearly the same as the metre. Yard ÷ 1000 = (metre ÷ 1000) - ·004 inch. The amount of confusion that would have been saved is almost incalculable.

The metric system usually carries with it the Centigrade scale on the thermometer, and here the whole English-speaking world should give no uncertain sound. I am not contending for any scale in chemistry or geology, but in meteorology it would be difficult to find a worse scale than the Centigrade. The plea that we must have just 100° between the freezing and boiling points does not hold; any convenient number of degrees would do. The Centigrade degree (1°·8 F.) is just twice too large for ordinary studies. The worst difficulty, however, is in the use of the Centigrade scale below freezing. Any one who has had to study figures, half of which have minus signs before them, knows the amount of labour involved. To average a column of thirty figures, half of which are minus, takes nearly double time that figures all on one side would take, and the liability to error is more than twice as great. I have found scores of errors in foreign publications where the Centigrade scale was employed, all due to this most inconvenient minus sign. If any one ever gets a "bee in his bonnet" on this subject, and desires to make the change on general principles, it is very much to be hoped that he will write down a column of thirty figures half below 32° F., then convert them to the Centigrade scale, and try to average them. I am sure no English meteorologist who has ever used the Centigrade scale, will ever desire to touch it. It is much easier and safer to convert the Centigrade scale to the Fahrenheit before any studies are made. As a matter of fact, European temperatures are a sealed book to active workers in meteorology on account of this unfortunate scale.

England and the United States may congratulate themselves, however, in the fact that European meteorology is almost flat. There are no low area or high area systems moving with regularity at any definite speed or in any definite direction, such as are experienced in the United States three or four times in a month. The rains in Europe are mostly sporadic, and do not accompany any well-defined low areas.

If any change is to be made, cannot the meteorological world come together upon a thermometer having its zero at -40° both Fahrenheit and Centigrade. This would be a most convenient scale, and would eliminate nearly all minus signs. The conversions from the old to the new would be very convenient by simply adding 40° to each. The conversion from the new Fahrenheit to the new Centigrade would also be extremely convenient by dividing by 1·8 instead of the present very puzzling system, and *vice versa*, Centigrade degrees + 1·8 would give the Fahrenheit value. This would obviate the difficulty of the minus sign, but there would still remain the fact that the Fahrenheit degree is by far better than the Centigrade.

Washington, D.C., December 18, 1895. H. A. HAZEN.

Apparatus for determining the Specific Gravity of Minute Fragments of Minerals.

THIS is a contrivance designed to facilitate the measurement of the specific gravities of minute fragments of minerals by means of a diffusion column of methylene iodide, as described by Prof. Sollas in NATURE, vol. xliii. p. 404, and vol. xlix. p. 211. There is no new principle involved in the construction of the instrument. It is merely the adaptation to this particular purpose of a well-known device for getting rid of the error due to parallax, such as is employed in Prof. Joly's spring balance for determining specific gravities, and the best form of tangent galvanometer. The index, which in this case is a fine wire, or fibre of any kind, is reflected in a mirror placed behind it, the coincidence of the fibre and its reflection showing that the eye of the observer is exactly on a level with the index.

In the drawing, *a* (Fig. 1) is a test tube containing the methylene iodide column in which the fragments of mineral under observation are immersed, together with two or more beads or fragments of mineral whose specific gravity is known. This is held by a clip, *b*, in a slot cut through the upper end of a thin piece of wood, some 12 inches high, fixed vertically to a firm base, so as to bring the test tube and its contents to a convenient height above the table. A slip of mirror, *d*, carrying a scale, *e*, divided in millimetres or any even graduations, is fixed vertically at the side of the slot, and the fibre is carried by a slider, *c*, which is shown separately in Fig. 2. This may be made of a strip of thin sheet copper, and has a "window" cut through it at *b*, so that the contents of the test tube may be seen.

The readings are taken by bringing the fibre successively on a level with the approximate centre of gravity of each fragment,

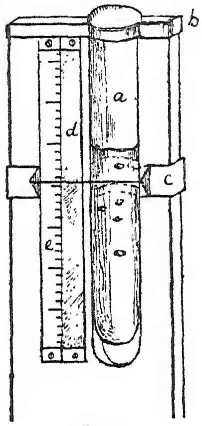


FIG. 1.

and noting the division of the scale cut by it, taking care that it coincides with its reflection in the mirror at each reading. The instrument might be improved by making the scale movable through a short distance vertically, so that one of the larger divisions of the scale might always be brought on a level with

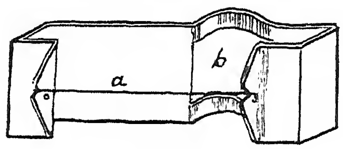

FIG. 2.

the uppermost of the beads or fragments used as indicators. The whole thing may be made at a cost of less than a shilling. It has been tried in the geological laboratory of the Royal College of Science for Ireland with satisfactory results.

T. D. LA TOUCHE.

Cactaceæ in the Galapagos Islands.

MR. HEMSLEY is mistaken in stating, as he does on p. 623 of NATURE for October 24, 1895, that Dr. G. Baur was attached to the U.S. Fish Commission Steamer *Albatross*. Dr. Baur had no connection with the *Albatross* Expedition of 1891, the object of which was deep-sea dredging, and only included an incidental visit of a few days to the Galapagos. Nor did Dr. Baur write the general sketch of that expedition, or have anything to do with the photographs which accompany it, as one might infer from a subsequent note by Mr. Hemsley on the Cactaceæ of the Galapagos (NATURE, November 14, 1895, p. 31).

As regards the Cactaceæ of those islands, I collected branches of *Opuntia* and of *Cereus* from Chatham and from Charles Islands; what became of those pieces I do not know, as they do not seem to have reached the hands of Dr. J. N. Rose, who described the plants collected at the Galapagos by the *Albatross* Expedition.

Mr. Hemsley will find that both Dr. Wolf and myself state that *Cereus* grows to 20 feet in height. Dr. Wolf also called attention to some striking differences he had noticed in the specimens of *Opuntia* and of *Cereus* he found on the different islands.

In stating his position, botanically speaking, regarding Dr. Baur's theory of the origin of the Galapagos, Mr. Hemsley would surely not give us to understand that *Opuntia* and *Cereus* are limited to Chili on the west coast of South America, as his second note (p. 31) seems to imply. ALEXANDER AGASSIZ.

Museum of Comparative Zoology, Cambridge, Mass., December 2, 1895.

[MR. HEMSLEY admitted, in NATURE of November 28, 1895, that he was in error in thinking Dr. Baur was attached to the U.S. Fish Commission Steamer *Albatross*.—ED. NATURE.]

THE VENEZUELA AND BRITISH GUIANA BOUNDARY.

THE sudden accession of an acute phase in the question of the boundary-line between British Guiana and Venezuela, has attracted the attention of the whole world to a controversy which has been proceeding intermittently for nearly a century. With its political aspect the pages of NATURE have no concern; but from another point of view it affords an opportunity for enforcing some of those scientific principles of geography, the ignorance or neglect of which has done much to embarrass the relations between neighbouring countries.

The fundamental error is to suppose that any piece of land on the face of the globe is so worthless that its ownership once claimed may be left undefined. So long as forest or plantation products alone, or mining alone, or any other partial potentiality of land is considered by itself, it is perfectly natural for colonists and governments to postpone expensive surveys of tracts that promise no immediate advantages, or to delay troublesome negotiations. In the end more trouble and more expense have to be faced, often in unexpected quarters.

Political geography is no longer a matter to be treated tentatively by politicians, any more than industrial chemistry is now a matter for the uninstructed experiments of tradesmen. It is the highest outcome of geographical theory, a theory which deals without a break with all terrestrial distributions, from the primary elements of geomorphology and climatology, to the adjustment of life to environment in the progressively more complex cases of plant, animal, and man. So little attention has been paid in this country to geography as a science with a definite purpose, and so few explorers have been equipped with even an elementary acquaintance with the principles of geography, that we gladly seize this opportunity to urge the importance of geographical theory as a guide to the prevision and prevention of frontier-disputes.

Two stages are necessary in arranging a frontier—drawing it on a map, and demarcating it on the ground. For the former purpose it is easiest to take a mathematical line, a meridian or parallel; for the latter some distinct physical feature, and of these there are only two which can be looked on as satisfactory—a watershed or a *Thalweg*. In practice the *Thalweg*, which is the line along which converging slopes meet, as the watershed is the line along which diverging slopes meet, means the central line of a river. The sea counts as neutral territory in all international affairs, and the coast-line requires no definition. The position of a parallel may be determined astronomically with great exactness, and, when marked on the ground by posts within sight of each other, is perfectly explicit; but it involves highly-skilled work and the agreement of two parties of expert surveyors. The case of a meridian may also be settled, but can rarely be free from the risk of rectifications being demanded, as more exact methods of determining longitude become available. Noteworthy exchanges of territory may thus be necessitated, perhaps involving hardships to individuals. A great mountain seems a peculiarly fitting corner-stone for the meeting of national frontiers, and is so used in the case of Mount Ararat; but Mount St. Elias has had to change its nationality by the rectification of the meridian of 141° W. Such a boundary-line as that between the southern part of Alaska and British Columbia, a line parallel to the coast, and ten leagues distant from it, represents perhaps the least scientific frontier on the face of the earth. It might be possible, when large scale maps are made of the fjord-riven coast, to draw this line on them; but only mutual goodwill and concessions could ever have allowed it to be even approximately marked on the ground.

In the particular instance before us, a map published by the Venezuelan Government in 1890, which it is impossible to reproduce on a small scale without the use of colour, shows the ten hypothetical western boundaries of British Guiana which have been put forward by one side or the other in the course of negotiations. Most of these lines are an outrage on geography, and it is difficult to believe that some of them were seriously put forward by the statesmen whose names they bear. We have been unable to find any British map showing these proposed boundaries, and it does not appear that our Foreign Office has published one. The boundaries in many cases cut natural features and mathematical lines at all angles and in irregular curves which it would be impossible either to describe verbally or to lay out accurately on the ground without a survey as minute as for a railway. These we do not require to dwell on, except in the way of pointing the moral that the results of geography should be officially recognised by Government departments more fully than has hitherto been the case. The Intelligence Division of the War Office is, in a sense, the Government Geographical Department, but it is concerned mainly with the practical work for the Army, and might well be supplemented by a more purely geographical office. It is true that the Royal Geographical Society is always ready to render help when called upon, and does not infrequently answer questions as to matters of fact. What is wanted, however, is rather an official geographer who may be consulted by the Government on matters of geographical theory as well as of fact, and who might be charged with the duty of preparing and keeping up to date an official geography of the British Empire.

The geographical conditions of the present boundary difficulty can be stated easily, so far as the main features are concerned; but the details are many and complicated. A boundary dispute in itself is a quite normal condition in South America. The boundaries of every republic in that continent are disputed; in several cases three neighbouring countries claim the same territory. It is impossible to draw a political map of South America, even on the smallest scale, that would be generally acceptable. In the case of Guiana, it is well to look at the physical condition of the land before tracing the contested boundaries. From the mouth of the Orinoko to the mouth of the Amazon the coast of South America runs nearly south-east, and the distance is 1000 miles. A line drawn from river to river, about 500 miles inland from the coast and parallel with the coast-line, contains the whole region known as Guiana. It consists of a gently rising plateau of Archæan rocks edged by very low plains of quaternary formation, bordering the Orinoko on the north, the Atlantic on the north-east, the Amazon on the south, and forming the llanos of the Rio Negro and Upper Orinoko on the south-west. The plateau bears a number of low mountain ranges, which have been made familiar by recent explorations; the Tumak-humak, Akarai, Pacaraima (including Roraima), Parime and Imataka, amongst others. The trade winds bring a heavy and regular rainfall to the whole eastern slope, causing it to be clothed with perhaps the richest and densest tropical forests of the world. On the top of the plateau, and on the western slopes, there is a reduced rainfall, and in accordance with this savannahs take the place of woods. Many large rivers carry off the surplus rainfall; of these we may name, on the north-eastern slope, from south to north, the Araguary, Oyapok, Maroni, Korentin, Essequibo (including the Mazaruni and Kuyuni), and, turning north-westward towards the sea, the Barama (or Guiana), Barima, and Amakuru. Every one of these rivers flows through dense primeval forests for the greater part of its course, and discharges on a muddy coast-line, which is rapidly growing seawards, thanks to the aid of mangroves.

On the south-western slopes the rivers are much longer,

and flow to the Amazon and the Orinoko, the two great river-systems being connected, as is well known, by the natural canal of the Casiquiare. The more westerly rivers flow, for the most part, through open savannah country; so that the water-shed of the plateau is much more accessible from the Orinoko on the west and north than it is from the Atlantic on the north and east. From Mount Roraima south-eastward *Thalwegs* of the upper tributaries of the Rio Branca form a political boundary to near the source of the Essequibo, after which the water-shed is a political boundary, the whole southern slope (except a small portion of the Rio Branco basin included in British Guiana) constituting Brazilian Guiana. From Roraima westward the whole area draining to the Orinoko River incontestably belongs to Venezuela. The present frontier disputes concern the forest-covered Atlantic drainage area, which is shared by the only three colonies remaining in South America—British Guiana on the west, Dutch Guiana in the centre, and French Guiana to the east. Here most of the boundaries are *Thalwegs*, *i.e.* the central line of rivers. There is no question as to Dutch Guiana, which is demarcated by treaty from British Guiana by the Korentin, and from French Guiana by the Maroni. But here certainty ends. The French and Dutch differ as to which of the upper tributaries of the Maroni should be taken as the boundary between Dutch and French territory. The Brazilian Government recognises the Oyapok as the French boundary toward Brazil; the French claim the Araguary, the space between the two rivers which flow nearly at right angles to each other being a triangle with 250 miles of coast as a base. The uncertainty of boundaries at the east of Guiana is simpler to understand, and easier to explain than that at the west. The claim of Venezuela is that British Guiana is bounded by the *Thalweg* of the Essequibo, and it is so represented on Venezuelan maps. The extreme British claim, on the other hand, is that the whole drainage area of the Essequibo belongs to the colony, *i.e.* that the boundary is the main watershed of the plateau as far as the Imataka range on the north, which runs parallel to and very near the Orinoko. In addition, there is a claim for the basins of the small rivers which occupy the triangular area between the drainage areas of the Orinoko and the Essequibo. If the western boundary of British Guiana were to be of the same type as those of the other colonies, it would require to be the *Thalweg* of a river flowing into the Atlantic, *i.e.* either the Essequibo, the Mazaruni, the Kuyuni (these three unite to enter the sea at a common mouth), or the Barama (Guiana), Barima, or Amakura.

It is now too late to suggest the solution of the boundary problem by geographical principles. Were it not so, a very interesting argument could be held as to how far the physical unity of a drainage basin is impaired by the obstacles to movement along the *Thalweg* due to cataracts interrupting navigation on the rivers, and forests obstructing progress on land. It is, in fact, very much easier to reach the upper basin of the Kuyuni branch of the Essequibo over the savannahs from the Orinoko than through the forests from the Atlantic coast.

All modern maps of Guiana—except the Venezuelan—follow what is known as Schomburgk's boundary, either in its original or in a modified form.

In 1840 the Schomburgk line first appeared on a sketch map, the topography of which was very inexact. From the Amakuru River in the north it ran along the watershed southwards, thus leaving the whole basin of the Barima in British Guiana. It so happened that the line ran nearly on the meridian of 60° W. as far as the Kuyuni River; and when the Barima was found to rise far to the west of that meridian, the line was often still drawn along it, instead of following the watershed as was intended. In 1886 the British Government modified the line by carrying it along the Kuyuni River to its source, and then for a short distance along the watershed, to Roraima.

The whole area within the Schomburgk line has been taken into effective possession by the Government of British Guiana so far as a tropical forest of such magnitude can be occupied. The Barima River was recently explored to its source by Mr. G. G. Dixon, and the account of his journey in the *Geographical Journal*, for April 1895, gives some idea of the difficulty of forcing a way through the woods. Much of the land is auriferous, and the real point of the present frontier difficulty lies in the value of Yuruari mines in the upper basin of the Kuyuni, at present occupied politically by Venezuela, and commercially by the nondescript cosmopolitan population always attracted to gold-fields.

It is this fact that makes it hopeless to expect the dispute to be settled by the geographical principles which forty years ago could have easily prevented it. The only alternatives are to base the rival claims on actual effective possession, or on the original rights which were recognised between the Dutch settlers in Guiana and the Spanish colonists of the Orinoko at a time when the geography of the district was practically unknown. The romantic story of British enterprise in Guiana is admirably told in Lucas' "Historical Geography of the British Colonies," vol. ii., a work of admirable clearness and brevity.

D'Anville's atlas of 1772 shows practically the whole of the disputed area as Dutch Guiana, but contemporary and later maps are very conflicting, and all of them being unofficial are of small value as evidence. The chart of Captain Edward Thompson, who took part in the first capture of the "Wild Coast" from the Dutch in 1781, marks the Barima as "the western boundary of the Dutch according to their claim," but does not suggest any boundary in the interior. The rights and wrongs of historic evidence will doubtless be fully investigated by those responsible for a decision, and the present dispute will probably be settled, as similar difficulties have been settled before, by some judicious compromise which will give both parties the inestimable benefit of a fixed and definite frontier. But similar disputes will continue to arise in other places, and their solution will be protracted and rendered difficult as long as unsurveyed territory is claimed by rival powers, spurred on by rival concessionaires and interested company promoters.

The recent International Geographical Congress decided that the time had come when all governments should be urged to make a map of their possessions on the uniform scale of 1 : 1,000,000, or about sixteen miles to an inch. If the governments of all countries were jointly to take this matter up, survey all unsurveyed lands which they claim, and submit the uncertain boundaries, which are not yet complicated by gold-mines, to an International Commission of Geographers, to be decided on the basis of the new map on purely geographical principles, the expense would be many times saved by the security which defined frontiers give, and a magnificent contribution to science would be effected.

HUGH ROBERT MILL.

DR. JOHN RUSSELL HIND, F.R.S.

It is with deep regret that we announce the death of Dr. J. R. Hind, whose name and whose work were possibly more familiar to astronomical students of the last generation than they are to those of to-day. By this we do not mean to imply that Dr. Hind had outlived his reputation, but that circumstances forced him to the front early in life and in connection with subjects that have long since ceased to attract or to interest. His claim to scientific reputation and remembrance will

mainly rest on his long connection with the *Nautical Almanac*, and the steady character for accuracy and efficiency that it maintained under his direction. But to the production of the *National Ephemeris*, while one is responsible, many contribute, and no one would admit more readily than the late chief of that department, how much he was indebted to the invaluable aid he received from such assistants as Messrs. Richard Farley, Godward, and others, or more willingly share the credit with those less well-known authorities. For these and other reasons, it is not a little difficult to assign to Dr. Hind his proper place among astronomers. He never devoted himself in any way to the higher branches of physical astronomy; the mathematical training that is sufficient for an engineer is not of that character that is required to advance our knowledge of planetary theories, or to assist their development by new functions. He will rank rather with the school of Argelander, to whom he was deeply attached, than with that of Bessel or Le Verrier. It is equally true that he never had occasion to employ the newer methods of observation that spectroscopy and photography demand, or to discuss the results obtained by their means, since the habits of his life and the direction of his work were settled before these methods of investigation were generally employed. Looked at, therefore, from the broader ground that astronomy now occupies, his scientific life seems somewhat cramped; but to conclude that his career was misspent, would be to read the history of astronomy for the last half-century very incorrectly. He was emphatically a practical astronomer, and whether as an observer or in making the mathematical work of others available for practical ends, he had few equals. He knew his capacity very well; he attempted nothing beyond his powers, and few men have made fewer mistakes.

As already intimated, Dr. Hind was originally intended for the profession of engineering, a science for which he had little taste, and it was fortunate for his subsequent career that circumstances permitted him to join the staff of the Royal Observatory. He was attached to the magnetical and meteorological department, at that time not fully organised nor even confidently regarded as a permanent part of the establishment. In those early days (1840), self-recording instruments were practically unknown, and meteorological readings and general attention to details required all-night sittings from the assistants. It was in these long watches that he acquired the habit of calculating comet and planetary orbits, undertaken at first with the view to keep himself awake, but which grew into a confirmed habit, and laid the foundation of his reputation as a computer. In 1844 he left Greenwich to take charge of Mr. Bishop's private observatory at Regent's Park. At that time Neptune was not discovered, and the first work that he began at that observatory was the formation of ecliptical charts of stars, three degrees each side of the ecliptic, with the view of detecting the object that disturbed the motion of Uranus. The comparison of these charts with the heavens led to the discovery of a number of small planets, which then were objects of interest and importance. Some variable stars, and a few comets of which he was the fortunate discoverer, extended his reputation and attested his zeal as an observer. Meanwhile the habits of calculation that he had acquired at Greenwich, were never allowed to lay dormant, and every *Nachrichten* as it came to England contained the orbit of a comet or a new planet which he had contributed to its columns. The history of ancient comets, the unravelling of the tedious descriptions of old or of Chinese astronomers, was his constant occupation, so that he acquired a masterly knowledge of the history of that portion of astronomy, and at one time we believe he had the intention of publishing an annotated *Pingré*. That such a work would have enhanced his reputation, and shown him to be the possessor of much curious information gleaned from many authorities, cannot be doubted, but the pleasure he derived from clearing up doubtful points, and adding to his own stock of information, were his only reward.

His facility as a computer led to his selection for the post of Superintendent of the *Nautical Almanac* when a vacancy occurred in 1853, through the death of Lieut. Stratford, and it will generally be admitted that he filled the post with credit to himself, and to the extended reputation of the important work of which he had charge. Official duties to some extent interfered with his private researches, but his industry was always very great. The list of papers to which Dr. Hind's name is attached in the Royal Society's "Index," though considerable, does not exhibit the full measure of his computational activity, because he did not often publish his results. An examination of this "Index" will, however, show the large variety of astronomical topics to which he turned his attention. And to this list we can only refer, without mentioning any particulars. But, in this place it would be ungrateful not to recall the fact that the deceased astronomer was the first contributor to our "Astronomical Column," and for some years the whole of the "Notices" were written by him. Neither can we undertake to give a complete list of the honours and awards that were showered upon him. He received the medals of both the Royal and the Royal Astronomical Society, the Danish Medal for cometary discovery, and the Lalande Medal on more than one occasion. He was made a Corresponding Member of the Institute of France, and many other foreign societies placed his name among their honoured members. The writer of this brief notice trusts that it may not be out of place for him to record his own sense of indebtedness for many acts of kindness and much valuable information that he has received at the hands of Dr. Hind. WILLIAM E. PLUMMER.

NOTES.

THE list of New Year Honours includes the names of two well-known men of science—Sir Joseph Fayrer, K.C.S.I., who has been made a baronet, and Prof. Prestwich, who has been knighted. If long and distinguished services to the cause of science count for anything, both Sir Joseph Fayrer and Prof. Prestwich have well earned the honours conferred upon them. Mr. H. H. Johnston, C.B., has been promoted to the Knighthood of the Bath; but this is probably more on account of his administrative work in recent years than for his explorations in Africa.

THE late Baron Larrey has left a bequest to the Paris Academy of Sciences for an annual prize of 1000 francs for the best treatise by an army doctor on any question of medicine, surgery, or sanitation.

PROF. A. ARCIMIS, writing from Madrid, informs us that at 6 p.m. on December 25, 1895, an earthquake was felt in some villages of the province of Orenne, Galicia, north-west of Spain. Some walls were cracked, the clocks stopped, and two small houses were thrown down.

THE commercial prospects of Hudson Bay are receiving much attention. Notice has been filed of application to the Canadian Parliament for a charter to construct a railroad from Calgary, on the Canadian Pacific Railroad, to Fort Churchill.

THE inhabitants of Zürich have rejected, by 39,476 votes to 17,297, a proposal submitted to them for the absolute prohibition of vivisection. On the other hand, a counter proposal of the Grand Council in favour of the protection of animals with due satisfaction to the demands of science was adopted by 35,191 votes to 19,551.

IT is announced in *Science* that Miss Helen Culver has signed papers giving 1,000,000 dollars to the University of Chicago, to

be used for the biological departments. This gift carries with it 1,000,000 dollars conditionally pledged by Mr. John D. Rockfeller on November 2. It is probable that a school of medicine will be established.

THE death has just occurred of Dr. George H. Kidd, distinguished for his researches and discoveries in surgery. We have also to record the death of Prof. A. von Brunn, Professor of Anatomy in Rostock University, and of Dr. Sickenberger, Professor of Botany and Chemistry in the Medical School at Cairo.

A MONUMENT to Dr. John Rae, the Arctic explorer, was unveiled on Monday, in St. Magnus's Cathedral, Kirkwall. The base of the monument is of Aberdeen granite, the pedestal of Peterhead granite, and the figure of Portland stone. The sculptor is Mr. Joseph Whitehead. On the pedestal is an inscription setting forth the dates of Dr. Rae's different geographical expeditions.

DR. W. HUGGINS, F.R.S., has been elected a corresponding member of the Berlin Academy of Sciences, and also of the American Philosophical Society, Philadelphia.

THE twenty-third annual dinner of the Old Students of the Royal School of Mines will take place on Friday, January 24. The chair will be taken by Mr. A. G. Charleton, and a number of well known men of science are expected to be present.

THE annual meeting of the Association for the Improvement of Geometrical Teaching will be held at University College, Gower Street, on Saturday, January 11. The morning meeting (at 11) will be devoted to the ordinary business of the Association. At the afternoon meeting (at 2), Dr. Larmor will read a paper on "Geometrical Methods," and visitors interested in the subject will be cordially welcomed.

WE learn through *Science* that the Astronomischen Gesellschaft has decided, because of the expense connected therewith, no longer to maintain a library. The announcement is made that the Society does not desire to receive any publications in the future, and that, with the completion of the thirtieth year of the *Vierteljahresschrift*, no exchange with other scientific bodies will be continued. Our contemporary also publishes the news that the Astronomical Observatory of the University of Berlin will probably be removed to Dahlem, to which suburb it is proposed to remove the Botanical Garden.

AN ingenious system of purifying atmosphere and regulating temperature is in operation at Chicago, for the switchboard room of the Telephone Company; where dust formerly interfered seriously with the connections on the switchboard. The air for the room is forced through a chamber, where it is thoroughly sprayed; then passed through rapidly rotating spiral coils, which strip it of superfluous moisture, and afterwards through a chamber kept at nearly uniform temperature by the use of ice or of heating apparatus, as may be required. Access to the switchboard room is through an ante-chamber; and the temperature of the room itself shows a variation of not more than two degrees in a month.

UPON application by the East Suffolk County Council, the Home Secretary has made the following order: The taking or destroying of wild birds' eggs is prohibited in the years 1896, 1897, and 1898, in the following places within the administrative county of East Suffolk—namely, the sea coast, beach, foreshore, sandhills, saltings, or salt marshes, situate between the sea or estuaries and the land side of the sea or estuarial wall, embankment, ditch, fence, or other artificial or natural boundary separating the same from the cultivated land, from the north side of the river Blyth to Landguard Point (excluding the estuary of the Alde above the ferry at Slaughden Quay, Aldeburgh).

THE Duke of Devonshire has not had to wait long for the further information which he expressed a desire to have, when the deputation waited on him on November 28 to support the appointment of a Statutory Commission for the establishment of a teaching University for London. It will be remembered that the Duke, in the course of the interview, expressed a desire for information with reference to the attitude of the graduates towards the scheme contained in the Report of Lord Cowper's Commission, and upon other points. A long memorial, signed by sixty representatives of colleges, medical schools, and other institutions, has now been forwarded to the Duke of Devonshire, as President of the Council. The memorial deals seriatim with the attitude of the graduates, the amendments proposed in the interest of external students, the suggested procedure by way of charter, and the rights of veto under the existing charter. It should assist the Duke to form an opinion as to the unreasonable and unconstitutional nature of the opposition to the scheme.

MR. LEON CLERC, Secretary of the Chambre de Commerce Française de Londres, writes as follows:—"The town of Dôle (Jura), the birthplace of Pasteur, has decided to erect a monument to that great man. A Committee, at the head of which is M. Félix Faure, President of the Republic, and many of the present Cabinet, Senators, and Deputies, has been formed, and a list of subscriptions opened throughout the civilised world. The French Chamber of Commerce in London has been requested to take the necessary steps to bring this subscription to the notice of the British public. The work of Pasteur has been fully recognised in England, where his admirers are very numerous, and many will cherish his memory to the end of their days. We feel certain that, in this universal manifestation of gratefulness towards a benefactor of mankind, Englishmen will respond liberally. Our President, M. Marius Duché, Monument House, E.C., in conjunction with the whole of our Committee, will be pleased to receive all donations, which will be acknowledged in the Press; and should any representative men desire to join our Committee, we shall be pleased to accept their aid."

DURING this month the first number of *The Journal of Experimental Medicine*, a periodical devoted to original investigations in physiology, pathology, bacteriology, pharmacology, physiological chemistry, hygiene and medicine, will be published by Messrs. D. Appleton and Co., New York. The journal will be devoted exclusively to the publication of original work in the experimental medical sciences, with special references to work done in America. It will doubtless stimulate scientific investigation, and should extend the influence of scientific medicine. The practitioner who wishes to keep abreast of the times will appreciate the value of such a publication. That the journal will be of high character, and truly representative of scientific medicine in America, is assured by the character of those whose co-operation has been secured. Dr. William H. Welch, Professor of Pathology in the Johns Hopkins University, is to be the editor of the new journal, and with him will co-operate a board of twelve associate editors, all of whom are eminent workers in scientific medicine. The journal will appear in, at least, four numbers during the year, and oftener when necessary.

ANOTHER periodical, the first number of which will appear in America this month, is entitled *Terrestrial Magnetism* an international quarterly journal to be published under the auspices of the Ryerson Physical Laboratory, University of Chicago, and edited by Dr. L. A. Bauer, with the co-operation of numerous eminent workers in terrestrial physics in many parts of the world. The journal will be devoted exclusively to terrestrial magnetism, and its allied subjects, such as earth currents, auroras, atmospheric electricity, &c. The magnetic needle has become such a promising instrument of research, not

only in terrestrial but also in cosmical physics, that the journal which is to be devoted to phenomena connected with it will appeal to a large class of investigators. To quote from the circular heralding the new publication: "No other mechanical means is so surely and so completely recording the physical history of terrestrial and cosmical changes as the self-registering magnetographs of our magnetic observatories, whereby the fitful tremors of the delicately suspended magnetic needle are being indelibly fixed on the sensitised sheet. On that paper, as Maxwell eloquently expressed it, the never resting heart of the earth is now tracing in telegraphic symbols, which will one day be interpreted, a record of its pulsations and its flutterings, as well as of that slow but mighty working [the secular variation] which warns us that we must not suppose that the inner history of our planet is ended."

THE *British Medical Journal* publishes the following list of prizes awarded by the Paris Académie de Médecine. The Barbier prize of £80, offered every year for the discovery of a remedy for an incurable disease, such as hydrophobia, cancer, epilepsy, cholera, &c., was not awarded to any of the ten competitors, but an "encouragement" of £20 was granted to M. E. Legrain for his work on the sero-therapeutic treatment of typhoid, and smaller sums were awarded to five others. The Henri Buignet prize of £60, for the best work on the application of physics or chemistry to medicine, was awarded to Dr. Chabrié for his memoir on the "Chemical Transformation of the Fundamental Substance of Cartilage during Ossification." The Adrien Buisson triennial prize of £420, offered for the discovery of a remedy for a disease hitherto looked upon as incurable, was divided among the following: £240 to Dr. Jarre for his work on the "Cure of Tic Douloureux of the Face by a New Surgical Method"; £80 to Dr. Chervin for his memoir on "Stammering and other Defects of Pronunciation"; £40 to MM. Wurtz and Marcano for their essay on "Leprosy: its Prophylaxis and Treatment"; £20 to Dr. Galliard for his work on "Pneumo-thorax"; £20 to Dr. Christiani, of Geneva, for his researches on the "Thryoid Body"; and £20 to Dr. Calvin, of the Medical Department of the French Army, for his work on "Chronic Paludism." The Chevillon prize of £60, for the best work on the treatment of cancer, was awarded to Dr. Repin for his work entitled "Contribution to the Study of a New Method of Treatment of the Malignant Inoperable Tumours: Toxitherapy." The Dauvel prize of £40 for the best work on myxœdema was divided between Dr. Combe, of Lausanne, and the Drs. Cristiani (M. and Madame), of Geneva. The Desportes prize of £52 for the best work on practical therapeutics was divided between Dr. Thibierge ("Therapeusis of Diseases of the Skin") and Prof. Delorme ("Disappearance of Neuritic Disorders, &c., by Localised and Forcible Compression"). The Huguier prize of £120 (triennial) for the best work on diseases of women, especially their surgical treatment, was awarded to Drs. S. Bonnet and P. Petit for their "Practical Treatise on Gynæcology. The Laborde prize of £200 was divided, Drs. Gouguenheim and Glover being awarded £100 for their "Atlas of Laryngology and Rhinology"; Dr. Chipault £60 for his "Operative Surgery of the Nervous System"; Prof. Reverdin, of Geneva, £20 for his essay on "Surgical Antisepsis and Asepsis," and Dr. Delbet £20 for his "Surgical Anatomy of the Bladder." A prize of £40 (Prix Adolphe Monbinne) was awarded to Dr. L. Petit for his book on "The Consumptive in the principal Countries of Europe." The Perron prize (£152) was divided among six candidates, Dr. Sabouraud getting the lion's share (£72) for his work on "Human Trichophytoses."

MR. DINSHAH A. TALEYARKHAN, who was President of the Tropical Section of the International Congress of Hygiene and Demography, Budapest, has sent us, from Baroda, two short notes referring to the discovery of the anti-toxin of snake-poison. The first of these notes was published in January 1890; but as we find no mention of a publisher or society upon it, we conclude it was issued privately, though it appears to have been brought before the medical faculty at Baroda. In the course of his paper, the author suggested that "the blood of a weasel must itself be an antidote to snake-poison," and remarked: "An alternative process may also be tried in first inoculating animal-blood with the virus of a serpent, and then preparing an extract for inoculation into the blood of a human being bit by a serpent." No experiments are described by Mr. Taleyarkhan, the object of the notes he has sent us being to call attention to his suggestions, made five years ago, and to compare them with the actions taken by Prof. Fraser.

THE question of the destruction of undersized fish and its prevention was by no means exhausted by the evidence laid before the Select Committee of the House of Commons, which was appointed to consider the subject in 1893. The evidence supplied to that Committee by the Marine Biological Association proved that the plaice of the English Channel belong to a smaller race, and reached maturity at a smaller size than those of the North Sea. Mr. J. T. Cunningham, one of the naturalists of the Association, has during the last year paid special attention to the further investigation of this subject in the North Sea, and has proved that the limits determined at Grimsby do not apply to the whole of that region. On the one hand, his evidence does not support the contention of the Germans that the plaice on their coast are a smaller race than those on the English side, but on the other hand he has found that the plaice landed at Lowestoft from the Dutch coast south of Texel are no larger than those of the English Channel, the extreme length of immature females being fourteen inches in the latter case, as against eighteen inches in the case of fish generally obtained in the North Sea. The difficulty of devising beneficial regulations to be applied to the fishing industry, while such important facts were still unknown, is sufficiently obvious.

RECENT attempts to improve the existing methods for the isolation of argon from the atmosphere have led to a closer examination of reactions in which nitrogen is directly absorbed by metals. The number of these known to be capable of readily combining with nitrogen at a red heat now includes magnesium, lithium, barium, aluminium, zinc, iron, and copper. Magnesium nitride, the properties of which were first pointed out by Brigled and Geuther, and which played an important part in the discovery of argon, is now well known, but our knowledge of other metallic nitrides is still incomplete. Metallic barium, which is readily prepared by the action of sodium at a moderately high temperature upon the double fluoride of barium and sodium, has just been shown by M. Limb (*Comptes rendus*, December 9), to absorb nitrogen energetically, and its use as a cheap means of preparing argon from air is suggested. Other nitrides have been prepared by a new method by MM. Rossel and Frank (*ibid.*). Calcium carbide, well powdered and mixed with finely-divided magnesium (aluminium, zinc, iron or copper), on heating over a Bunsen burner, with free access of air, gives calcium oxide, together with a nearly quantitative yield of the corresponding nitride. But the most remarkable results have been given by lithium. This metal was recently shown by M. Guntz to absorb nitrogen with incandescence at temperatures below a red heat. It has now been shown by M. Deslandres (*ibid.*), and M. Guntz (*Comptes rendus*, December 16), that this absorption takes place slowly in the cold. The latter exposed about ten grams of lithium over sticks of caustic soda to a slow current of air; the product after four months consisted of seventy-six parts of nitride, twenty parts of hydroxide, and only four parts of metallic lithium. M. Deslandres proved the same fact under somewhat different conditions by allowing a

confined volume of nitrogen to act on metallic lithium. The absorption was slow, but was so complete that the characteristic bands of the nitrogen spectrum entirely disappeared. M. Deslandres compares the reaction to the slow absorption of oxygen by phosphorus, and points out that as a reaction of nitrogen this is unique.

AN interesting contribution, by M. Osmond, to the existing knowledge on the molecular structure of hardened steel appears in the *Bulletin de la Société d'Encouragement* for November. He states that in highly carburised steels, containing more than 1·3 per cent. of carbon, quenched at temperatures above 1000°, there are two constituents, A and B, which differ widely in their properties. The constituent A is the ordinary, hard, strongly magnetic substance of which hardened steel containing 1 per cent. of carbon is almost exclusively composed. Its hardness is greater than that of orthoclase. B, on the other hand, is only about as hard as fluorspar, and, as far as can be judged by a study of its properties while mixed with A, is non-magnetic. M. Osmond, however, has been hitherto unable to prepare B free from A, although by quenching steel containing 1·6 per cent. of carbon at a temperature of from 1000° to 1100° in ice-cold water, he has obtained a mixture of A and B in about equal proportions. This mixture is comparatively very feebly magnetic. The constituents both contain carbon, and exist side by side in separate polyhedra. The author concludes that B is the allotropic form of iron (denoted γ), which is especially stable above 860°, and is present to the exclusion of the other forms of iron in steels containing 25 per cent. of nickel, or 12 to 13 per cent. of manganese, these steels being non-magnetic. The hard constituent A would then be the allotropic form β. The research will be hailed by the allotropists as affording most important evidence in favour of their theory.

A PAPER on the temperature variation of the thermal conductivities of marble and slate is contributed to the *American Journal of Science* by B. O. Peirce and R. W. Willson. The net result of their investigation is that such a temperature variation does not exist; in other words, that marble and slate conduct heat equally well at all temperatures. This result is of some importance to the physics of the earth's crust, and the manner in which it was arrived at displays some ingenuity. Two faces of a slab of marble or slate were kept at different temperatures, and the fall of temperature between one surface and the other was determined by means of thermopiles. Now it is notoriously difficult to determine the temperature accurately at a certain point, and borings lead to errors in estimated depth. So the expedient was adopted of slicing the slab into a series of layers pressed together, between every two of which a thermocouple was introduced. The interstices were only a few tenths of a millimetre, and experiments with different intervals proved that the error in the temperatures observed did not exceed one or two degrees Centigrade. On plotting the temperatures and distances, the temperature was found to have fallen uniformly throughout the slab. If the conductivity had been higher at higher temperatures, the fall on the hot side would have been more decided. The temperatures ranged from 350° C. to zero.

ATTENTION may be drawn to a translation, in handy form, of Prof. Hering's well-known addresses on "Memory as a General Function of Organised Matter," and on "The Specific Energies of the Nervous System." The little volume is issued by the Open Court Publishing Company of Chicago, as part of the Religion of Science Library, at a price of 15 cents.

A CONCISE account of the work of Priestley, Scheele, Cavendish, and Lavoisier, in connection with "The Discovery of Oxygen, and its Immediate Results," which appeared recently in the *Pharmaceutical Journal*, has been reprinted and published in the form of a pamphlet, obtainable at the office of our contemporary.

A "MUSEUM REPORT," containing a descriptive list of the donations to the Museum and Herbarium of the Pharmaceutical Society during 1893–94, has been prepared by Mr. E. M. Holmes, Curator of the Museum, and published by the Society. The catalogue contains interesting notes concerning the more important donations, and the complete list of donations to the Herbarium, in which the plants and plant products are arranged in alphabetical order, should prove of practical value.

THREE new volumes have lately appeared in the comprehensive Aide-Mémoire series published jointly by MM. Gauthier-Villars and G. Masson, Paris. One is "Applications Scientifiques de la Photographie," by M. G. H. Niewenglowski. We have long expected the publication of a book on this subject, but the one now before us is satisfactory. No account is given of the remarkable results obtained in astronomical photography, and the photography of solar and stellar spectra is only mentioned in a few words. In fact, the author has not treated his subject in the broad scientific manner it deserves, and there is yet room for some one to write a really good treatise on it. The volume by M. X. Rocques entitled "Analyse des Alcools et des Eaux-de-vie," just published in the same series, should prove of service to analytical chemists; while the third of those lately received—"La Topographie," by Lieut.-Colonel P. Moëssard, is an excellent manual on maps and their construction, containing concise descriptions of triangulation, levelling, and cartography.

THE last number of the *Bollettino* of the Italian Seismological Society contains an interesting paper by Dr. G. Agamennone, on the earthquake of Paramythia (Epirus) during the night of May 13–14, 1895. The official accounts state that 269 houses were destroyed, and 262 more were rendered uninhabitable; that seventy persons were killed and fifty wounded; but Dr. Agamennone believes that these figures refer only to the district of Paramythia. The area including all the villages where houses were damaged is elliptical in form and contains about 400 sq. km., the longer axis being directed N.N.E. and S.S.W. The centre of this area lies near the villages of Dragani and Carvounari, where the intensity of the shock was between ix. and x. of the Rossi-Forel scale. In this district, the ground was fissured in several places. The shock was felt, though slightly, at Zante, which is 180 km. from the epicentre; and the pulsations were registered by several of the Italian seismographs, and also by the horizontal pendulum at Nicolaiew, about 1250 km. from Paramythia.

THE additions to the Zoological Society's Gardens during the past fortnight include a Burchell's Zebra (*Equus burchelli*, ♀) from South Africa, presented by the Hon. W. Rothschild; a Common Badger (*Meles taxus*), British, presented by Mr. Thomas B. Place; a Rough Fox (*Canis rudis*) from Demerara, presented by Captain J. Ernst; a Blue and Yellow Macaw (*Ara ararauna*) from Brazil, presented by Mrs. Alec. Tweedie; two Hoary Snakes (*Coronella cana*), two Puff Adders (*Vipera arietans*) from South Africa, presented by Mr. J. E. Matcham; an Anamolous Snake (*Coronella anamola*) from Brazil, presented by Mr. Frank Summers; a Nilotic Monitor (*Varanus niloticus*) from North Africa, deposited; two Ornamental Lorikeets (*Trichoglossus ornatus*) from Moluccas, two Forsten's Lorikeets (*Trichoglossus forsteni*) from Sumbawa, purchased; a Cactus Conure (*Conurus cactorum*) from Brazil, received in exchange; a Southern River-Hog (*Potamochœrus africanus*) from East Africa, presented by Mr. Henry M. C. Festing; a Golden Eagle (*Aquila chrysaëtus*) from Scotland, presented by Mr. Osgood H. Mackenzie; a White-crowned Mangabey (*Cercocebus æthiops*, ♂), a Green Monkey (*Cercopithecus callitrichus*, ♂) from West Africa, deposited; two Red-sided Tits (*Parus varius*) from Japan, purchased.

OUR ASTRONOMICAL COLUMN.

ROTATION OF JUPITER.—Most of the determinations of the rotation period of Jupiter have been made by observations of surface markings between latitudes 45° N. and 35° S., and little has been known as to the conditions of rotation near the poles. This is due to the fact that conspicuous and sufficiently definite spots are chiefly confined to the equatorial regions of the planet, and partly to the unfavourable conditions under which the poles are presented to us. Some important observations, however, bearing on the rotation in high latitudes, have been secured by Mr. Stanley Williams with the aid of a $6\frac{1}{2}$-inch Calver reflector (*Ast. Nach.*, 3325). On October 10, 1892, a short dusky streak, almost oblong in appearance, was observed quite close to the north limb of Jupiter, and reaching at least as far as 85° N. Other streaks of similar appearance were subsequently observed, and frequent observations of the times of mid-transit were made. Confirmation of the results has been obtained by an examination of several photographs of the planet taken at the Lick Observatory about the same period, the markings being sufficiently distinct for measurement. Generally speaking, the visual agree very closely with the photographic results, the mean rotation period derived by the two processes only differing by about two seconds. The mean result for the rotation period of the surface material of Jupiter, between north latitudes 40° and 85°, is 9h. 55m. 38·9s. ± 1·20s., this being the length of a sidereal rotation expressed in mean solar time. The following statement illustrates the degree of accuracy obtained:—

	h.	m.	s.		s.	
Spot *a* ...	9	55	33·7	±	1·32	(77 rotations)
Spot *b* ...	9	55	43·8	±	2·25	(41 ,,)
Spot *c* ...	9	55	39·7	±	0·60	(252 ,,

Mr. Denning's value for a spot in latitude 35° N., namely, 9h. 55m. 39s., agrees very closely with the foregoing, and differs by only a few seconds from the period deduced from observations of the red spot.

Supplementary details, which are given by Mr. Williams, indicate that the positions of markings on Jupiter may be determined with quite as much accuracy from photographs as by the best micrometrical measurements in the telescope.

THE PARALLAX OF α CENTAURI.—As part of a discussion of the meridian observations of α Centauri, made at the Cape Observatory during the years 1879–1881, Mr. A. W. Roberts has deduced a new value for the parallax of this interesting system (*Ast. Nach.*, 3324). Mean places for the two components have been computed by applying corrections for proper motion and orbital motion, and assuming a parallax of 0″·75. The errors of a systematic nature, which cannot be certainly accounted for, are believed to be due to an erroneous value of the refraction depending upon the temperature. Disregarding these, and adopting the aberration constant determined by Chandler, 20″·50, the parallax of α Centauri, from declination measures alone, was found to be 0″·81 ± 0″·05. From the right ascension measures alone, the value 0″·66 was calculated. Solving for both coordinates, the resulting value for parallax is 0″·71 ± 0″·05. This corresponds to a little over $4\frac{1}{2}$ light-years and shows a marked agreement with the parallax 0″·75 found by Drs. Gill and Elkin in 1882 from measures made with the heliometer.

NEW VARIABLE STAR OF THE ALGOL TYPE.—*Harvard Observatory Circular*, No. 3, announces that the star B.D. + 17°·4367, magnitude 9·1, and approximate position for 1900, R.A. 20° 33′·1, Decl. + 17° 56′, is a variable of the Algol type. The change in brightness appears to be rapid, and the range of variation to exceed two magnitudes.

THE NATURE OF THE PHYSIOLOGICAL ELEMENT IN EMOTION.

PROF. A. C. WRIGHT contributes an interesting paper "on the nature of the physiological element in emotion" to *Brain* (parts 70 and 71), the object of which is to apply the results obtained by Gaskell's observations on somatic and splanchnic nerves to the study of the emotions. Prof. Wright begins his paper by taking as an example the phenomena observed in a kitten confronted with a strange dog, and shows that such an emotional stimulus would call forth in the kitten a regular series of reflex responses: first of all, through the involuntary visceral efferent nerves; then the semi-involuntary muscles, such as those of the face, would be called into action; and, lastly, there would be reflex response of certain parts of the voluntary muscular system. The essential features to be recognised in this example and in every emotional reaction are—the origination of the emotion in a violent sensory stimulus, a condition of extreme neural tension in the reflex centre, and an overflow of neural energy into different paths. This overflow takes place first into channels associated with involuntary muscle, then into those associated with semi-voluntary muscle, and lastly into those associated with voluntary muscle. The physiological essence of the emotion is to be found not in the visceral reflex actions, but in the high neural tension of the reflex centre which gives rise to these actions. In childhood sensory stimuli call forth in each case responses both of involuntary and voluntary muscle, while with increasing age the outflow of neural energy from the reflex centre becomes more and more restricted to paths associated with voluntary muscle. As a result of such transformation we get purposive voluntary action. The author notices the *à priori* necessity for some system of control of the reflexes, since "if each minimal stimulus were to evoke a separate reflex movement in an organism which was endowed with a sensitiveness at all approaching that of the human organism, life would be a mere chaos of muscular movement." Voluntary muscles react to the slightest stimuli, but involuntary muscular actions are only called out by intense stimuli, or by a summation of slighter ones. High neural tension in the reflex centre is therefore necessary for these reactions of involuntary muscles, and all such high neural tension is attended with a sense of distress. The replacing of the "generalised somatico-visceral reflexes of inexperience and childhood by the specialised purposive reflexes of experience and adult life" . . . "is not so much a question of substituting one variety of reflex for another, as it is a question of substituting a condition of low neural tension for a condition of high neural tension."

PHOTOGRAPHY AND CHRONOGRAPHIC MEASUREMENTS.[1]

IN chronographic measurements in physiological experiments, photography has been in constant use for several years, and the methods are well known. I have extended recently the method of what may be called photographic chronography to measuring the velocity of projectiles. On former occasions I have shown that to obtain the best chronographic results, magnetic and solenoidal arrangements should be avoided, since by their use a time lag is introduced. The following chronographic method depends entirely on light. Two sources of light at a suitable distance apart throw two beams of light on to a sensitive plate, carried on the carriage of a tram chronograph. By means of lenses, the beams of light are caused to form two sharp images on the plate in a vertical line, one above the other; a tuning-fork trace is also made on the plate; if the plate traverses, when the beams of light are not interrupted, on development, two black parallel lines appear on the plate; but if, during the passage of the plate, the beams of light are cut by any solid object which shuts off the light, then on development two gaps are seen to exist. The distance between these markings when interpreted in terms of the fork trace, give the velocity of the object which cuts through the beam of light. The method was illustrated by allowing a projectile to pass through the focus where the convergent beams of light from two sources of light cross.

Another method was also shown in which the projectile cut through two thin screens placed in the paths of the beams of light, and so opened a passage for the light. In this case two parallel lines are found on the plate, one longer than the other; the difference of their lengths, when duly interpreted, gives the velocity of the projectile; when the distance between the screens is considerable, the beams of light have to be reflected on to the chronograph by mirrors. FREDERICK J. SMITH.

[1] A Note on a Lecture given at Oxford, October Term, 1895.

ATMOSPHERIC ELECTRICITY.[1]

It is hardly possible to imagine that the first experimenter who obtained an electric spark sufficiently strong to produce a sensible sound should not at once have been struck by the fact that he was in the presence of thunder and lightning on a small scale. We find, indeed, in various writings from the early days of electrical machines a number of suggestions that the thunderstorm is an electrical phenomenon; but to Benjamin Franklin belongs the merit of having perceived that a direct experiment was needed to prove what so far was only a guess. In an article entitled "Opinions and Conjectures concerning the Properties and Effects of the Electrical Matter arising from Experiments and Observations made at Philadelphia, 1749," the following passage occurs:—

"To determine the question whether the clouds that contain lightning are electrified or not, I would propose an experiment to be tried where it can be done conveniently. On the top of some high tower or steeple place a kind of sentry-box, big enough to contain a man and an electrical stand. From the middle of the stand let an iron rod rise and pass, bending out of the door, and then upright 20 feet or 30 feet, pointed very sharp at the end. If the electrical stand be kept clean and dry, a man standing on it, when such clouds are passing low, might be electrified and afford sparks, the rod drawing fire to him from a cloud.

"If any danger to the man should be apprehended (though I think there would be none), let him stand on the floor of his box, and now and then bring near to the rod the loop of a wire that has one end fastened to the leads, he holding it by a wax handle: so the sparks, if the rod is electrified, will strike from the rod to the wire, and not affect him."[2]

The experiment suggested by Franklin was successfully performed in Marly (France), by D'Alibard, on May 10, 1752,[3] in London by Canton, in Spital-square, on July 20, 1752, and by Wilson, in Chelmsford, Essex, on August 12 of the same year. Franklin himself describes having used a kite in Philadelphia in a letter dated October 19, without giving the date of his observations. But this must be supplied in some passage which I have not been able to find, for Rosenberger ("Geschichte der Physik," vol. ii. p. 316) mentions that it was done in June.

Franklin's disbelief in the dangerous character of the experiment must have received a severe shock when he heard of the death of G. W. Richmann, who, in the year 1753, was killed by an electric discharge drawn from the clouds by means of a kite.

The thunderstorm is the most impressive effect of atmospheric electricity, though it is rivalled in beauty by the aurora, and in interest by the many phenomena of daily occurrence, which are only made perceptible to us by proper instruments. In a lecture delivered before this Institution on May 18, 1860, Lord Kelvin described the delicate electrical appliances constructed by him for the more accurate observation of atmospheric electricity. The problems then for the first time clearly stated, gave a powerful and still lasting impulse to the investigation of atmospheric electricity, and though no decisive answer can be given to all the questions raised in that lecture, recent researches have brought us somewhat nearer to their solution.

Observations which may be made every day and at every place have shown that the earth is electrified, whatever the weather may be. In the language of the older theories, which we cannot as yet altogether abandon, we say that the earth is covered with negative electricity, or, in modern phraseology, we express the same idea by the statement that we move about in an electrified field, that electric lines of force stretch through the air from the ground, from our bodies, and from everything which is exposed to the sky overhead. The strength of this electric field is not at all insignificant. If we wish to produce it artificially between two parallel plates kept at a distance of one foot, we should have to apply an electromotive-force sufficient—and sometimes more than sufficient—to light up the incandescent lamps which illuminate our dwellings. The electric force is comparatively weak in our country, but 50 volts per foot are constantly observed, and 100 volts are not uncommon; but in dryer climates the amount of the force may be considerably in excess of these figures.

[3] *Ibid.*, p. 107.

If we fix our minds on the lines of force starting from the surface of the earth, we are at once led to ask, Where is their other end? Do they curve round and back again to earth? Do they end in the dust which everywhere surrounds us, or do they reach up to the clouds? Do they pass through the clouds and end where invisible particles separate the sunset red from the midday blue? Or, finally, do they leave the earth altogether, and form intangible bonds between us and the sun, the stars, the infinity of space? These are not idle questions, and we cannot be said to have solved our problem unless some definite answer is given to them. The last-mentioned view, propounded originally by Peltier, and latterly supported by Exner, is the simplest. If we could allow that the earth, once electrified negatively, could remain electrified for ever, the corresponding positive electrification being outside our atmosphere altogether, the chief difficulty of atmospheric electricity would be removed, and the normal fall of potential at the surface would be explained by the permanent negative electrification of the surface.

Unfortunately this view, to be tenable, has to assume that the atmosphere is a complete non-conductor to the normal electric stress, and this is known not to be the case. We know of several causes which break down the insulating properties of air. If two pith balls are electrified and repel each other, and a match be lit in their neighbourhood, the pith balls come together, showing that they have lost their charge, and consequently that the flame of the match has destroyed the insulating power of air. It is not only the flame itself which conducts, but also the gases rising from the flame.[1] The following experiment will prove this. In Fig. 1, A represents a metallic tube bent round at the upper end, and containing at its lower end a Bunsen burner in metallic contact with the tube, which is also connected to an electroscope. The tripod, T, which supports the tube, is insulated by blocks of paraffin. A Leyden jar, L, on a separate support, is placed so that the knob stands at about the level of the upper part of the tube, which acts as chimney to the flame. The knob of the jar may be a few inches away from the opening of the chimney, and not necessarily in a line with it. The experiment succeeds, although the gases rising from the burner may not come into contact with any part of the jar. The jar is charged, and care must be taken that no fibres of dust attach themselves either to the jar or chimney. I have found it convenient to join a piece of amalgamated zinc to the end of the chimney. Under these circumstances the charge of the jar will be found to leak across to the tube, and the leaves of it will diverge. If, as in Exner's form of electroscope, the leaves, on reaching a certain divergence, discharge by forming a

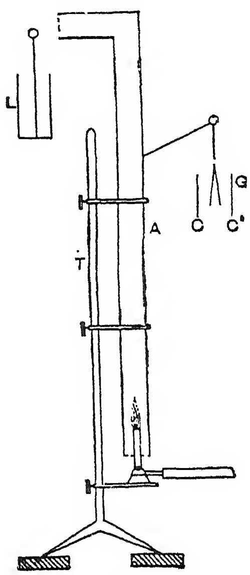

Fig. 1.

[1] The most complete investigation of the conduction of gases rising from flames is contained in a series of papers by Giese (*Wiedemann's Annalen*, vol. xvii.).

contact with earth-connected plates, C C′, the charging and discharging can be watched for a long time. It will be noticed that the flame, being altogether surrounded by a tube of the same potential, cannot be active in this case, but the conductivity must be due to the gas as it escapes from the chimney.

It follows from these experiments that every fire burnt on the surface of the earth, and every chimney through which products of combustion pass, act like very effective lightning conductors, and would consequently discharge, slowly but surely, any electrification of the surface of the earth. The peculiar immunity of factory chimneys against damage by lightning appears from statistics collected by Hellmann in Schleswig-Holstein,[1] for while 6·3 churches per thousand were struck, and 8·5 windmills, the number per thousand of factory chimneys was only 0·3.

Franklin was acquainted with the action of flames; he also discovered that no charge can be given to a red-hot iron ball, a fact which seems to have been forgotten until re-discovered in our own times by Guthrie. Franklin also tried the action of sunlight, but obtained no result. Had he performed the experiment with carefully-cleaned zinc, he would have anticipated one of the most striking of Hertz's discoveries. We now know that a negatively-charged surface will discharge into air when illuminated by strong violet light, and sunlight will be sufficient with specially sensitive materials. This action has been investigated in detail by Elster and Geitel, who have not, however, succeeded

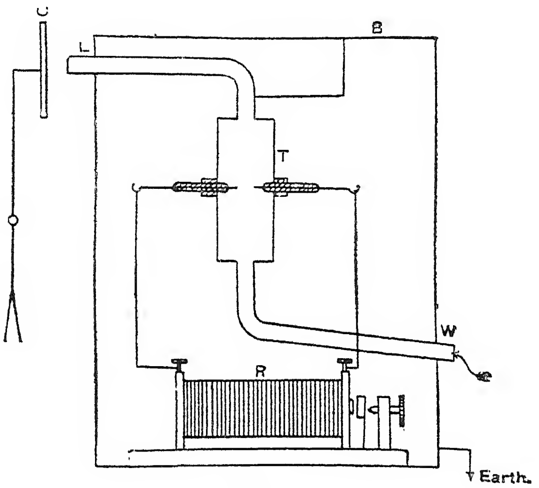

FIG. 2.

in obtaining results with sunlight acting on such bodies as we know the earth's crust to be made of. So far, then, we have no experimental evidence to include light as an active agent in the phenomenon of atmospheric electricity.

We possess in the electric discharge itself a very powerful, and probably very generally active means of breaking down the insulating power of air. Some of the experiments (*Proc. Roy. Soc.*, vol. xlii.) which I described some years ago to prove this, were objected to on the ground that it might not be the discharge itself, but the ultra-violet light sent out by the luminosity of the discharge, which was active. The following form of the experiment conclusively shows that the discharge acts independently of light.

In Fig. 2, R represents a Rhumkorff coil entirely surrounded by a metallic box, B, which is connected to earth. The terminals of the coil lead to two electrodes inside a metallic tube, T, which is also kept at zero potential. This tube is arranged so that a current of air can be blown through it. The air, on escaping through the tube, is made either to impinge on or to pass near a metallic plate connected to a charged electroscope. Under these circumstances, the electroscope is not discharged either by a current of air alone, or by the coil alone. But as soon as the air is blown through the apparatus while the sparks are passing and then made to impinge on the plate C, the electroscope is instantaneously discharged. The experiment succeeds when a plug of cotton-wool is inserted at W, to stop the action of the dust; but a plug of cotton-wool at the other end diminishes the action so much, that I am doubtful whether the effect then really exists there. I am, so far, not inclined to believe that the action is due to dust, but rather that the cotton-wool acts in increasing very considerably the interval which elapses between the time at which the spark acts and the time at which the sparked air passes out of the tube. The effect may be observed even though the tube L is lengthened by an addition of another piece 3 feet or 4 feet long.

Several phenomena, one of which had been known for a long time, can be explained by the fact that the electric discharge changes the condition of the gas into a state similar to that of gases rising from flames. It is mentioned, for instance, by Faraday that electric sparks are liable to succeed each other along the same path, and it is known that the same holds for lightning flashes, facts which themselves point to a higher conductivity of air along the path of the previous discharge. A curious instance of a similar effect is afforded by lightning conductors, which are sometimes put up to protect overhead leads used for conveying a high tension current. Owing to the obvious impossibility of connecting the leads directly to earth, a small air gap is interposed, the idea being that the air gap will act as an insulator for the current the leads are intended to carry, but that if during a thunderstorm the potential rises sufficiently high to be dangerous, equalisation may take place through the air gap to earth by means of a small spark. So far, the air gap answers its purpose, but as soon as a spark passes through the gap, it destroys the insulating power of the air, and the main current consequently takes a short-cut through the gap. At Pontresina, in the Engadine, lightning conductors put up in this way are so sensitive that a flash of lightning several miles away causes a small spark by induction, and instantaneously puts out every electric lamp in the town.

If we accept the view that an electric discharge destroys the insulating power of the gas, it follows that the outer regions of the atmosphere must conduct, for we have ample reason to suppose that electric currents are passing continuously through those regions. The aurora borealis in the arctic regions is, according to Nordenskiöld's observations, a permanent phenomenon, and the diurnal changes of terrestrial magnetism show that in our latitudes electric currents traverse the air above us. However small a conductivity we may assign to the atmosphere, the earth could not remain electrified inside such a shell of partially conducting gases. Lord Kelvin drew the same conclusion in the Royal Institution lecture, on the assumption that gases at much reduced pressures cease to insulate. We may leave it an open question whether the normal electric stress could in itself cause a discharge in the outer regions; but we cannot deny that under existing conditions these regions do not insulate, and Lord Kelvin's argument still holds good.

But the question of the ending of the lines of force—in other words, the location of the positive charge corresponding to the negative electrification of the surface of the earth—can only be solved by balloon or kite experiment, and we may briefly mention the more important results which have so far been obtained.

Observations made up to heights of about 1000 feet seem to indicate a strengthening of the electric field—*i.e.* the fall of potential per metre is greater at a height of, say, 200 metres than on the surface of the earth. The observations of Dr. Leonhard Weber (*Elektrotechnische Zeitschrift*, April 1888) bring out this point clearly. In one case the fall of potential at a height of 350 metres was found to be six times that at the earth's level. This increase is in itself not surprising, if we remember that every particle of dust raised from the ground must itself be negatively electrified, and probably the observed increase in the electric force is sufficiently accounted for by the presence of electrified dust.

Observations made at greater heights in balloons, on the other hand, seem clearly to indicate that this increase soon ceases, and that a diminution already takes place at moderate heights. Thus the observations of Dr. O. Baschin (*Meteorologische Zeitschrift*, September 1894) gave for the fall of potential in volts per metre the numbers 49, 28, 13 at heights of 760, 2400, 2800 metres respectively, and at a height of 3000 metres no measurable fall at all could be obtained. These observations were made in clear weather. The balloon afterwards passed over a layer of clouds, and strong electric effects were noticed. Similar observations had been previously made by

[1] "Veroffentl. des Kgl. Preuss. Stat. Bureaus," 1886, p. 177, quoted by Bebber, "Meteorologie," p. 245.

others (Andrée, Le Cadet, and Bornstein), and though the subject is by no means exhausted, we may take it as provisionally established that the lines of force of the normal electric field of the earth end within the first 10,000 feet or 15,000 feet. This result is of great importance, for it shows that in fine weather there must be a layer of positively electrified air permanently above us. Currents of air in this layer must affect the field as we observe it, and possibly the daily period may be due to changes in the currents of air at a moderate height. A fact discovered by Exner is of importance in connection with this subject. Observing at three different places (in a field close to Vienna; in St. Gilgen, on the Wolfgangsee; and on the hills near Venice), he found that whenever there was a strong south wind, with a clear sky, the normal electric force was always increased, and sometimes considerably (*Wiener Akad. Sitzungsberichte*, vol. xcvi., 1887).

The daily changes show, with few exceptions, a remarkable uniformity at different places. There are in general two maxima of potential—one at 8 or 9 o'clock in the morning, and one in the evening. The evening maximum is the most marked, while at some places, and especially near towns, the morning maximum disappears. The same general features of the daily variation have been found to hold at a number of European stations, at Cape Horn, Melbourne, and in the Northern Arctic regions. If the variation is separated into two—one having a period of 24 hours, and the other of 12 hours—the latter is found to agree in phase at widely different places on the earth's surface, while the former is found to vary to a much greater extent, and hence to be probably more affected by local circumstances. The remarkable researches of Hann have given a similar result for the diurnal variations of the barometer, and we may reasonably conclude that the semidiurnal variation of atmospheric electricity is connected with the same circulation in the upper regions of the atmosphere which shows itself in the corresponding changes of pressure.

In addition to the more regular periodic changes, the electric stress observed in fine weather shows marked differences on different days and at different seasons. With respect to these, the researches of Prof. Franz Exner (*ibid.*) have led to the important result that there is a close connection, direct or indirect, between the amount of aqueous vapour present in the atmosphere and the fall of potential observed at the surface of the earth. If p_0 be the pressure of aqueous vapour present in centimetres, Exner deduces the equation for electric force P

$$P = \frac{A}{1 + kp_0},$$

where $A = 1300$, $k = 13{\cdot}1$.

The formula agrees very well with observations in which the vapour pressure varied between 0·23 and 0·95, and it is especially to be remarked that it is the amount of vapour and not the humidity which determines the electric force. Observations made by Mr. E. Drory during a journey round the world fit in very well with Exner's formula, and observations made at such widely different places as Suez, Albany, Sydney, Colombo, and Penang showed a fall of potential practically identical with that calculated from the above formula, though the same constants were taken and the vapour pressure varied between 0·8 cm. and 2·2 cm.

Messrs. Julius Elster and Hans Geitel (*Wiener Akad. Sitzungsberichte*, vol. ci., 1892) have followed up this research. Their investigations have shown a satisfactory agreement with Exner's formula, if the mean values of a number of observations in which the vapour pressure is approximately the same, is considered. But individual numbers differ very widely from the mean, so that the formula cannot be used to predict the normal fall of potential on any particular day. There is, perhaps, nothing surprising in the great divergence of such individual results if it is considered that we only observe the moisture near the surface of the earth, but are ignorant of the total amount of water in the column of air over the district in which the observations are carried out. The same authors have shown that an equally good agreement can be obtained if, instead of the amount of aqueous vapour, we take the intensity of active radiation as the determining circumstance. The light might be supposed to act on the general surface of the earth, as it does according to Hallwachs' observations on a metallic body, dissipating a regular charge. There are some difficulties in the way of this explanation, the most serious being the absence of experimental evidence that sunlight actually does act in the manner indicated on any substance forming part of the earth's surface. It is impossible at the present time to enter more fully into this subject, but attention must be drawn to the very important indirect result, that there seems to be a connection between ultra-violet radiations and the amount of aqueous vapour present in the air.

The phenomena of atmospheric electricity have been studied at the mountain observatory established on the "Sonnblick," in Salzburg, at a height of 3100 metres.

The important result has been established that the electric force is singularly constant. The great differences observed at low level between the electric field in summer and winter, or on dry and wet days, seems to be completely absent, and these facts tend to support the conclusion derived from balloon observation. that the positive ends of the lines of force are situated at a height of something like 10,000 feet.

Brief allusion must be made to some of the causes which alter to a marked extent the normal fall of potential. As the surface of the earth is negatively electrified, it follows that dust carried up by the wind must be electrified, and it is found, indeed, that in violent dust storms the laws of force near the surfaces are altogether distorted and reversed in direction. Werner Siemens (*Pogg. Ann.* cix., 1860; *Meteorologische Zeitschrift*, 1890, p. 252) could, while standing on the top of one of the pyramids during a strong wind, charge an improvised Leyden jar sufficiently to obtain strong sparks. A casual observation of Elster and Geitel (*Ziele und Methoden*, p. 11) may prove significant. On March 7, 1889, the temperature in Wolfenbüttel was rising from -10° C. to $+2^{\circ}$ C., a cirrus layer covering the sky. The fall of potential changed in the course of four hours from 1302 volts per metre to -1200 volts, that is. from a very exceptionally high fall to an equally strong gradient in the other direction. Although the atmospheric circumstances were anomalous, they seem in themselves not sufficient to account for the anomalous electrical effects, and the authors suggest that a possible explanation may be found in a violent dust storm which on the previous day was observed in Alexandria.

Fogs are generally found to increase the normal fall considerably, so that the drops of water must be taken as positively electrified.

Waterfalls considerably disturb the electric condition of the air in their neighbourhood, the air surrounding the fall being charged negatively, sometimes to considerable distances.

Whether clouds in themselves are always electrified is very doubtful; they no doubt disturb and generally weaken the fall of potential at the earth's surface, but this may only be due to a displacement of the positively-electrified layer which balloon observations have shown to exist at a height of from 10,000 feet to 20,000 feet. While a cloud discharges rain, the electrical effects in the neighbourhood of the place are the same as that in the neighbourhood of a waterfall. The explanation is probably the same in the two cases, and by means of experiments, alluded to further on, we may reproduce the negative electrification of air under similar circumstances.

Measurements of the electrification of falling rain or snow, simple as they appear at first sight, are beset with very serious difficulty. We owe the most complete investigation on the point to Messrs. Elster and Geitel (*Wiener Sitzungsberichte*, vol. xcix., 1890). They find no regularity in the electrification, though positive signs slightly preponderate with snow and negative signs with rain.

The approach of a thunderstorm announces itself by characteristic cumuli clouds, and the general atmospheric condition favourable to their formation is felt by many persons of nervous temperament. Many of us are accustomed to hear that "there is thunder in the air." Whatever the special feeling of "thunder" may be due to, it cannot be an electrical effect, for electrical instruments delicate enongh to detect a small fraction of the normal force, give no indications of the approach of a thunderstorm, and it is only when the cloud has begun to discharge rain or hail that strong electrical effects are noticed. During the thunderstorm the electroscope is, of course, much disturbed, and there are frequent and violent reversals of its indications.[1] The fact that no effects are observed at the surface of the earth during the approach of a thunder-cloud does not prove that there is no electrical separation, for we may imagine two oppositely electric layers at different levels producing a strong

[1] Weber, *Elektrotechnische Zeitschrift*, vol. x.; Elster and Geitel, "Ueber einige Ziele und Methoden Luftelektrischer Untersuchungen," Wolfenbüttel, 1891.

electric field between them, but only weak effects outside. That some such things may possibly occur is indicated by observations made in mountain districts, where violent electrical disturbances are observed previous to the formation of clouds (Trabert, *Meteorologische Zeitschrift*, 1889, p. 342). The cumulus cloud, from which the lightning strikes out, is nearly always associated with a cirrus layer above it, and the flash occurs more frequently upwards or sidewards between the clouds than down to earth. Under such circumstances it is clear that instruments on the surface of the earth can only very partially indicate the nature and distribution of electrical stress in the neighbourhood of the cloud.

Thunderstorms seem always to be connected with a vortex motion, and meteorologists distinguish two kinds of thunderstorms. The first kind forms in the outlying portions of a large cyclonic system. The storms which occur in winter are mostly of this nature, and the vortex necessary for its formation is of the nature of a secondary disturbance. The thunderstorm which forms in summer, on the other hand, makes its own vortex, and is of a much more local character than that which is produced round a previously established barometric depression. The summer storm is much influenced by the character of a district. There are certain configurations apparently favourable to its formation, as is clearly brought out by the charts which have been made representing their frequency.

The route travelled over by the storm is affected by mountain ridges, and rivers also seem to offer a peculiar impediment. Many of them are brought to an end either along their whole front, or only part of it, when they reach the banks of a large river.[1]

Some curious problems are presented by the detailed structure of lightning flashes. Although these lie outside the range of the present lecture, reference must be made to the very beautiful photographs of lightning flashes taken both in this country and abroad. The ordinary forms which lightning takes are familiar to all; but a good deal of mystery still surrounds the so-called globular lightning. The manner in which this form appears is best described in the words of eye-witnesses.

Dr. A. Wartmann gives to the Physical Society of Geneva the following account of what he saw:[2]—"At half-past six o'clock in the evening I drove from Versoix to Genthoud. On the Malagny road I heard the coachman say he did not know where he was. His eyes were so much fatigued by the frequent and intense lightning discharges, that he was blinded, and could not, even in the intervals, see the road, in spite of the good lanterns alongside. I stepped on to the box and took the reins. We had barely passed the principal gate of the grounds of Dr. Marcet, when I became conscious of a bright and lasting luminosity behind me. Thinking it was a fire, I turned round, and saw, at a distance of, roughly, 300 metres, a ball of fire of about 40 cm. diameter. It travelled in our direction with a velocity about equal to that of a bird of prey, and left no luminous trail behind. Just as the ball had overtaken us, about 24 metres to our right, it burst with a terrific noise, and it seemed to me as if lines of fire started from it. We felt a violent shaking, and remained blinded a few seconds. As soon as I regained power of distinguishing objects, I saw that the horses had turned at a right angle to the carriage, with their chests in the hedge, with drooping ears and all signs of great terror. I returned on the following day to the place where I had seen the ball explode, but could find no sign of any damage. At a distance of 100 metres I found that a group of three trees, bordering a wood, had their upper branches singed, but it is not possible to say whether this was due to the discharge which I had seen."

The following is a translation of an account given by Mr. H. W. Roth (*Meteorologische Zeitschrift*, 1889, p. 231):—"During the thunderstorm of May 19, 1888, at about 6 p.m., a flash of lightning took effect which seems to me remarkable from a physiological point of view. The dealer Werner, from Ellerbruch, and his son (sixteen years old), with a one-horse conveyance containing rags, were on the road which leads from here to the village of Ottensen, about three miles away in a southwesterly direction. The father had been left a little behind, and the son was occupied in giving bread to the horses, when he found himself suddenly surrounded by light, and noticed a fiery ball, about the size of his fist, moving towards him along the back of the horse. Then he lost consciousness. He felt no concussion. The father, on approaching, saw the horse's limbs still contracting, and at first he thought his son was dead, but succeeded, after considerable efforts, in bringing him back to life in about three-quarters of an hour. The horse was dead."

Some curious statistics have been collected, especially in Germany, as to the damage done by lightning flashes. That damage seems to have increased to an enormous extent within the last fifty years, and although in cases of this kind statistics may easily be at fault, there seems no doubt about the reality of the fact, which may find an explanation in the partial cutting down of forests in those parts where thunderstorms chiefly occur. When lightning strikes into forests, it selects certain trees by preference. Thus, in the principality of Lippe, taking the percentage of beeches struck by lightning as unity, that for other trees is as follows:—Oak 48, spruce fir 5, Scotch fir 33.

The St. Elmo's fire, a continuous discharge from points and sharp angles, is often observed on board ship and in mountain districts during a storm. Its appearance was considered a sign of the approaching end of the lightning, and was looked upon with favour by the ancient sailors in the Mediterranean Sea, who gave to it the name of Castor and Pollux. There was another appearance called Helena, a bad omen, which by many is believed to have been another form of the St. Elmo's fire, and the present name has been stated to be a corruption of the word Helena. Some support is given to this view by the fact that the Emperor Constantine built a castle in the Pyrenees, which he named after his mother, Helena, and this castle seems to be referred to occasionally as St. Elne or St. Elme. But it is much more probable, as argued by Dr. F. Piper (*Pogg. Ann.*, vol. lxxxii. p. 317), that the word is derived from St. Erasmo, a bishop who came from Antiochia, and suffered a martyr's death at the beginning of the fourth century. He seems to have been specially considered the patron of Italian sailors. Churches and castles in Naples and Malta were called St. Erasmo and St. Ermo, and Ariosto describes St. Elmo's fires as St. Ermo's fires. The electric discharge which goes under this name has a different appearance according as it is the positive or negative electricity which escapes, and both kinds occur with about equal frequency.

Although we have not yet arrived at any satisfactory theory of atmospheric electricity, some progress has been made, and this account would not be complete without a short account of the views taken by men of science on the subject. The number of theories proposed is very considerable. Dr. Suchsland,[1] in a pamphlet published in 1886, gives an account of twenty-four, to which he adds one—his own. The year 1884 alone has given birth to four theories.

We may group the theories according to the origin they assign to the source of energy which is involved in the formation of the electric field. All the work we can perform is either derived from the sun or from the earth's rotation. There is, as far as I know, only one theory—that of Edlund—which makes the earth's rotation in space responsible for the separation of electricities in the atmosphere. But Edlund's views are not tenable in theory, and, even granting his deductions, the normal fall of potential should, according to the views of the author, have a different sign in the polar and equatorial regions, which is contrary to the observed fact. This theory does not, however, exhaust the possibility of explaining atmospheric electricity as a phenomenon of electromagnetic induction, and it is not disproved that in some form or other the rotation of the earth's magnetic field may play a part in the origin of the electric field. The theories which take solar radiation as the source of the energy divide themselves into several groups. We may think of a direct thermo-electric or actinic action, but there is, so far, no experimental support to such views. One of the earliest and most natural suppositions is the belief in evaporation as a source of electrification. This was Volta's theory, and experiments have at various times been produced in its support; but, so far, no one has been able to invalidate Faraday's conclusion that whenever electrification seemed to appear as a consequence of evaporation, it was really due to secondary causes, such as the friction of the liquid spray against the sides of the containing vessel. Rejecting Volta's theory, there is nothing left but the belief in some form of contact or frictional electricity either between drops of water and air, or water and ice, or any two of

[1] Bebber, "Meteorologie," p. 255; Bornstein, *Archiv der Seewart*, viii., 1835.

[2] *Arch. des Sci. Phys. et Nat.* (3) vol. xxi., 1889. The above account is translated from the *Meteorologische Zeitschrift*, 1889.

[1] "Die Gemeinschaftliche Ursache der Elektrischen Meteore und des Hagels," H. W. Schmidt, Halle-a.-S.

the various bodies present in the atmosphere. The possibility of contact electricity between a solid or liquid and a gas, is not quite easy to submit to the test of experiment. If we rub two solid bodies together, we may, by separating them, investigate the electric field produced; but, supposing we have a drop of water surrounded on all sides by air, the water may be covered with an electric layer of, say, positive electricity, the air in contact with the water with the opposite kind, and it is not at all clear how we could experimentally demonstrate the difference of potential between the air and the drop which is thus produced. A current of air flowing past the drop might carry away some of the negative layer, and in this way an electric field may be established while clouds are forming, but the conditions necessary for an experimental demonstration would be very difficulty to realise. Two methods have been devised which practically demonstrate some form of contact electricity between gases and water.

Lenard, wishing to imitate the electric field observed in the neighbourhood of waterfalls, has established by careful experiment a number of important facts, which are all consistent with the following explanation. If we imagine two oppositely electrified layers at the surface of a drop of water such as has been referred to, and if the drop falls on to a layer of the same liquid, or if similar drops impinge on each other, the difference of potential produced by the fusion of the surface layers becomes greater than is consistent with equilibrium. For, taking the case of drops falling into a mass of water contained in a cylindrical vessel, the extent of surface between air and water is not increased by the falling drops, and we must imagine that surface to be already covered with a sufficient electrical sheet to establish the required difference of potential, The electrification of the drops is, therefore, not wanted, and a change in the distribution takes place. The natural supposition would be, that this equilibrium would be restored very quickly through the surface of the water, but a certain time seems to be required for this. Meanwhile, the strong current of air which in Lenard's experiments is brought down with the water drops carry some of the electricity away, the water remaining positive. More recent experiments of Lord Kelvin's, with air bubbling through water, point similarly to contact forces between gases and liquids, and in these experiments also it appears that a considerable time is required to establish electric equilibrium between a gas and a solid. Lenard finds very important differences caused by small impurities in the water, the water acting much more strongly when it is pure. If it contains as much salt as is contained in the sea, the effect is reversed, and the air becomes positively electrified. The explanation which is given above is practically that of Lenard, whose observations have been confirmed and further extended by Prof. J. J. Thomson. These experiments, no doubt, account for the behaviour of air in the neighbourhood of waterfalls, and they probably also explain the negative electrification of air in the neighbourhood of districts in which rain is falling. The strong positive electrification of mist may also be due to the same cause.

There seems to be no doubt that the formation of a cloud is often accompanied by electrical effects. A few years ago, descending from the Dent Blanche, I found myself, after sunset, at a height of about 12,000 feet. A current of air was apparently blowing up the valley which stretches from Evolena towards Ferpecle, and I could observe a cloud condensing below me at a height a little below the snow-line. As night came on and we continued our descent over the glacier and down the valley, a series of electric discharges were noticed between the cloud, which was lying in a deep-cut valley, the sides of the mountain, and the blue sky overhead. Here the moist air was evidently streaming through the cloud, depositing its moisture in the form of drops, and it seemed the most natural explanation at the time that the air left the cloud in an electrified state.

But while by means of experiments we have been able to produce some of the phenomena of atmospheric electricity, we have other important effects which cannot be accounted for in so simple a way. The electric discharges during a thunderstorm give evidence of electric fields, which could hardly be explained by contact electricity between drops of water and air alone. The fact that thunderstorms are nearly always connected with the formation of hail, and Faraday's experiments showing that water rubbing against ice becomes negatively electrified, is made use of in the theories of Sohnke and Luvini. It is quite likely that there is some truth in these theories. Their weak point lies in the difficulty of seeing how particles of ice and water can be first sufficiently mixed to allow of friction, and then become sufficiently separated to produce an electric field of such magnitude as we know must exist in a thunder cloud.

It is to be remarked, however, that the laws of contact electricity must be applicable to gases as well as to solids, and that if water becomes positive when rubbing against air, and negative when rubbing against ice, there must be a strong contact difference between ice and air. In other words, it does not matter whether there is direct friction between ice and water, or whether the air forms an intermediate body. We may imagine air rising through a cloud containing drops of water negatively electrified, and then passing through an ice cloud having its negative electricity increased, thus leaving the ice and water particles at a difference of potential which may, by a fusion of the drops, increase sufficiently to produce a lightning discharge. This seems to me the most plausible theory which, in the present state of our knowledge, can be formed. As regards the permanent negative charge of the earth's surface, the time has not yet arrived for forming a definite opinion. Although we know that the earth, once electrified, would gradually lose its charge into the atmosphere, yet we can express no opinion as to the rate at which the loss is going on. That loss may be exceedingly slow, and consequently equilibrium might be attained by a very small preponderance of negative electricity brought back to its surface through some cause or other. Rain, as has already been mentioned, is more frequently electrified negatively than positively in our own climate, and though we do not know how far this holds in the tropical belt, it is at any rate possible that the surface of the earth may in this way alone make up for the loss. We may also reasonably think that Lenard's observation on salt water may account for the permanent charge. Every wave that breaks into spray under the action of a strong wind would leave the water negatively electrified, the air carrying away the positive charge. It would be of great interest to possess observations on atmospheric electricity on board ship while waves are breaking in the neighbourhood. So far we have only Exner's observations to guide us, who found, while observing at Lavinia, in Ceylon, that the spray from breaking waves affected the indications of the electrometer, proving its positive electrification (*Wiener Akad. Sitzungsberichte*, vol. xcviii.).

But although the loss of electricity from the earth's surface may be very slow, it is equally possible that it is considerable. We shall not be able to treat this question satisfactorily until we have some clearer notion of the causes of the aurora. We know that the aurora implies electric currents, and the circuit of these currents may lie completely within the earth's atmosphere, and have nothing to do with the observed fall of potential near the ground. It is also possible that the body of the earth forms part of the electric circuit, and if that is the case, there must be across different parts of the surface an outward and inward flow of positive electricity. Such a discharge could not fail to influence the phenomena we have discussed, and it seems probable that we should have some evidence derived from observation if the aurora was always accompanied by discharges through the earth's surface. Except in the polar regions, these auroræ do not seem to affect the normal fall of potential. There is a third view we may take as to the circulation of electric currents indicated by the aurora: the return current may take place in space outside the earth's atmosphere. A good deal might be said in favour of this view, and the rotation of the earth's magnetic field in space might be a sufficient cause for the production of these currents; but this is not the place to enter further into this question.

Calculations made from observation on the height of the aurora have generally resulted in an altitude of from 100 to 200 miles, except in the polar regions, where the aurora seems occasionally to descend to a much lower level. It has also been noticed that auroræ are associated with certain bands of cirrus clouds, and this seems to indicate that although the luminous phenomenon is sufficiently intense to be observed at only great heights, yet the electric phenomena may descend to the level of the cirrus.

As regards the connection between the aurora and the sun-spot period, further observations in the polar regions are needed. On the one hand, we have Paulsen's[1] statement, derived from observations in Greenland, to the effect that the greatest number

1 Paulsen, "Danske Videnskab. Selskabs Forhand.," 1889. (I have not seen the original memoir, but only an abstract in the *Jahrbuch der Astronomie und Geophysik*, 1890.)

of auroræ are seen when sun-spots are at their minimum, that is, at a time when in our own latitudes the number is smallest; and, on the other hand, we have Nordenskiöld's observations, which seem to point in the opposite direction. In a publication which contains much important matter on the geographical distribution and form of the aurora borealis, Nordenskiöld contrasts the appearances he has observed in the *Vega* during the winter of 1878–79, passed in the Behring Straits, with that previously observed in 1872–73 to the north of Spitzbergen. According to this author, the auroræ, during the minimum sun-spot period in 1878–79, were "hardly worthy of his notice by the side of those observed in 1872–73." But although only faintly luminous, the auroræ of 1879 were persistent and regular in shape. They did not affect the magnetic field, and seem to show a regular and continuous, though weak, electric discharge. The arc and streamers in 1872 were much more brilliant and much more irregular. Some objection may be raised against these observations, in so far as they refer to different places, and local circumstances may have affected the phenomenon; but in the face of the very careful description he gives us, we cannot as yet accept Paulsen's results without further confirmation.

The problem of atmospheric electricity, like that of terrestrial magnetism, presents special features in the arctic regions, and until we possess a greater number of observations in those little accessible parts of the earth's surface, many important problems cannot be satisfactorily solved. Arctic and antarctic expeditions are of interest to scientific men, not because they care much whether we get a few miles nearer the pole, but because a well-conducted party collects invaluable information on its journey. Although much remains to be done in the regions surrounding the north magnetic pole, our knowledge in the southern hemisphere is almost disgracefully inadequate, and it is to be hoped that before long a well-equipped expedition may fill up to a certain extent the large gaps in our electrical and magnetical knowledge which at present stop so many of our researches.

But although investigations to be conducted in the arctic regions are of primary importance, we may do much nearer home in extending and completing existing information. Instrumental appliances and methods of observation, originally put into a satisfactory state by Lord Kelvin, have been improved, especially by Mascart, Exner, Elster, and Geitel. One of our most crying wants at present is a series of continuous observations by means of self-registering instruments in places where the neighbourhood of a town, or other local circumstances, do not interfere with the normal changes. The Greenwich Observatory, to which we look for help in such matters, is placed in the difficulty that the daily variations there observed are markedly different from those in the majority of places, and it is probable that the nearness of London is fatal to any generally useful series of observations of atmospheric electricity being conducted in our national Observatory.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE annual general meeting of the Association of Technical Institutions will be held at the Goldsmiths' Hall on Friday, the 24th inst.

THE Senate of University College, Liverpool, on the joint recommendation of Profs. Lodge and Hele Shaw, have appointed Mr. Alfred Hay, B.Sc., of University College, Nottingham, to the Lectureship on Electrotechnics, vacant by reason of the election of Mr. F. G. Baily to the chair of Electrical Engineering at the Heriot-Watt College, Edinburgh.

MR. L. F. GOLDSTAND has presented the Royal Agricultural College, Cirencester, with the sum of £200 for the institution of three silver medals annually, to be awarded according to results of the final examination for the diploma, at the discretion and decision of the Principal. The donor has requested that the medals be styled the "McClellan," the "Harker," and the "Goldstand," respectively; and the Principal, on behalf of the Governing Body, has accepted and ratified the donation.

THE eighth annual report, just published by the National Association for the Promotion of Technical and Secondary Education, is a mine of statistical and other information referring to the development of educational organisation in Great Britain. Substantial progress is recorded in the work of technical education; and it appears that of the £744,000 annually available in England alone, £600,000 is being spent on education. In the year covered by the report, 7252 scholarships and exhibitions, of the total yearly value of £40,598, were offered by thirty-seven counties. A large section of the report is devoted to summarising the recommendations of the Royal Commission on Secondary Education.

AMONG recent appointments and nominations abroad, we notice the following:—Dr. Hürthle to be Extraordinary Professor of Physiology at Breslau; Dr. N. Busch to be Director of the Botanic Garden of the University of Dorpat; Dr. K. G. Huefner, Professor of Organic and Physiological Chemistry at Tübingen, to succeed the late Prof. Hoppe-Seyler at Strassburg; Dr. Bauschinger, of Munich, to succeed the late Prof. Tietjen as Extraordinary Professor of Astronomy at Berlin; Dr. Anton F. v. Eiselsberg, Professor of Surgery at Utrecht, to be Prof. Braun's successor at Königsberg; Dr. H. Nichols to be Lecturer in Psychology in the Johns Hopkins University, Baltimore.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science for August 1895 contains: On the variation of *Haliclystus octoradiatus*, by Edward T. Brown (plate 1). Some 154 specimens were examined, 120 of these were perfectly normal but 34 afforded either cases of congenital variation, or showed regeneration of organs after destruction or injury. Most of the abnormal forms are figured.—On the collar-cells of Heterocœla, by George Bidder (plate 2). Observations were made on *Leucandra aspera*, *Sycon raphanus*, *S. compressum*; this last was found best suited for examination under high powers during life, its collar-cells are among the largest, if not as large, as any known. The protoplasm of these cells is in life greenish, and they have nearly the form and relation to each other of full corn-sacks standing side by side in a granary. The living collar is invariably an almost perfect cylinder, very little constricted at its base. As to Sollas's membrane, the statements of Vosmaer and Pekelharing, which the author once thought erroneous, he now confirms, there is no normal union of the collars, the membrane is only to be met with in "paraffin sections."—The metamorphosis of Echinoderms, by Henry Bury (plates 3–9). With the view of clearing up some of the differences in observation and opinion of the more recent observers of the metamorphosis of this group, the author has worked out as far as possible the metamorphic changes of at least one form of larva in each of the five classes of Echinoderms; for reasons given, the metamorphosis of Synapta is written in greater detail than that of the rest. As to the relation of the Echinodermata to the Enteropneusta, "there seems to be a chain of evidence of their connection, which though not indeed conclusive—that embryological evidence alone can never be—is at least as strong as that which binds together any two of the great subdivisions of the animal kingdom."—A criticism of the cell-theory; being an answer to Mr. Sedgwick's article on the inadequacy of the cellular theory of development, by Gilbert C. Bourne. The article of Prof. Sedgwick here criticised appeared in the *Q.J.M.S.* for November 1894.

The number for November 1895 contains:—On the distribution of assimilated iron compounds, other than Hæmoglobin and Hæmatins, in animal and vegetable cells, by Dr. A. B. Macallum (plates 10–12). After some preliminary remarks on the special literature of the subject and references thereto, the author details his methods of study. This portion of the memoir is very instructive, not only for the facts recorded, but for the hints given; chlorophyll yields no evidence that it contains iron, and it is mentioned incidentally that species of Monotropa remain colourless when fixed in solutions of corrosive sublimate. The greater part and sometimes the whole of the assimilated iron in the cells of the higher forms of animal life is held in the nucleus, in the chromatin of which it is chiefly found, and the same is true of the nuclei of all the higher vegetable organisms; it is rarely found in the cytoplasm of the cells, but full details of such occurrences are given. An important section is devoted to the occurrence of assimilated iron in special forms of life, such as in protozoa, fungi, bacteria, and the Cyanophyceæ.—On the structural changes in the reproductive cells during the spermatogenesis of Elasmobranchs, by J. E. S. Moore (plates 13–16). The author establishes a long series of structural homologies found before, during, and after the synaptic phase in the repro-

ductive cycles of both animals and plants, and so close is their correspondence, amid a host of complex structural details, that it is in the highest degree improbable that the two series of phenomena can have been independently evolved; and whatever the synapsis may eventually turn out to be, it is evidently a cellular metamorphosis of a profoundly fundamental character, which would appear to have been acquired before the animal and vegetable ancestry went apart, and to have existed ever since.—Notes on the fecundation of the egg of *Sphærechinus granularis*, and on the maturation and fertilisation of the egg of *Phallusia mammillata*, by M. D. Hill (plate 17). In these forms there is no egg astrosphere or egg centrosome; both these structures are brought into the ovum by the spermatozoon, and they give rise by division to all the subsequent astrospheres and centrosomes throughout ontogeny. There is consequently no such thing as a "quadrille."—Further remarks on the cell-theory, with a reply to Mr. Bourne, by Adam Sedgwick, F.R.S.

Symons's Monthly Magazine for December contains a climatological table and summary for various selected stations of the British Empire, for the year 1894. Australia records the highest shade temperature, viz. 107°·0 at Adelaide, on November 26, and it was the dryest station. In the twelve years for which the annual summaries have appeared, this station has yielded the highest maximum in ten years, Melbourne in one, and Calcutta in one. The lowest temperature in the shade was recorded at Winnipeg, -46°·1 on January 24. This station has never been equalled for lowness of absolute shade temperature, and has only twice failed to record the greatest mean daily range; the variation during the year amounted to 141°·9. The dampest station was Esquimalt, where the mean humidity was 88 per cent.; London comes next, being 81 per cent., and both these places were the most cloudy, the average amount being 6·3. The least cloudy stations were Bombay and Grenada, where the average amount was 4·0. The greatest annual rainfall, 77·5 inches, occurred at Colombo, and the least, 18·1 inches, at Winnipeg. The Cape of Good Hope observations were unfortunately missing.

L'Anthropologie, 1895, Tome vi. No. 4.—Quatenary deer of Bagnères-de-Bigorre (Hautes-Pyrénées), by Édouard Harlé.—A careful examination of the mandible has led the author to the conclusion that the animal to which it belonged was neither a reindeer nor a stag, but that it must be considered a variety of the fallow-deer; and its presence in conjunction with *Elephas primigenius*, *Rhinoceros tichorinus*, and the reindeer, at the foot of the Pyrenees, is a fact of some interest.—Note on the age of metals in the Ukraine, by Baron de Baye. The progress of civilisation was not uniform in the north and south of Russia in Europe. In the district south of a line which corresponds very closely with the 50th parallel of latitude, it has been found that the use of metals was known at a very early date, whilst the Stone Age continued for a much longer period in countries to the north of this line. Baron de Baye is careful to explain that the term "Scythian," which he uses freely in connection with the mounds and the various bronze articles found in them, does not express an anthropological unit, but is used in a purely geographical and ethnological sense. The numerous tribes, however, comprehended under this name had the same civilisation, practised the same arts and the same funeral rites, and left behind them similar archæological remains.—Anthropological observations on the tumuli and worked flints of the Somali and the Danakil, by Dr. Jousseaume. The tombs are constructed of rough stones, more or less spherical or ovoid in shape, and of various sizes. The flints are arranged by the author in four groups, the first of which is represented by a single specimen in the form of a wedge. The second group is spatulate, rather long, very thick, and always larger at one end than at the other. The flints included in the third group are discoidal, and of various sizes; while the fourth group includes all those that are lance-shaped.—Infantilism, feminism, and the hermaphrodites of the ancients, by Henry Meïge. In this section of his paper the author treats of feminism, of which a very beautiful example came under the observation of Prof. Charcot at La Salpêtrière.

Bollettino della Società Sismologica Italiana, vol. i., 1895, No. 6.—Earthquake of Paramythia (Epirus) during the night of May 13-14, 1895, by G. Agamennone (see p. 205).—The Guzzanti microseismoscope, by G. Guzzanti.—Notices of Italian earthquakes (April–May 1895), referring chiefly to the Florentine earthquake of May 18, and to the pulsations of the earthquake of Paramythia of May 13-14.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 28, 1895.—"The Expansion of Argon and of Helium as compared with that of Air and Hydrogen." By Dr. J. P. Kuenen, Professor of Physics in University College, Dundee, and Dr. W. W. Randall, Lecturer in John Hopkins University, Baltimore, U.S.A.

The gas-thermometer used for these experiments was such as could be easily heated by means of a "Ramsay and Young" vapour-jacket. It consisted of a bulb sealed on to a capillary tube, which in turn was sealed on to a wider tube, provided with a mark. This mark is situated just outside the heating arrangement, immediately below the capillary tube. The inner mercury-surface is made to coincide with this mark, and both this one and the outer surface are read on a scale with a telescope. The readings were duly corrected for capillary action, expansion of glass and mercury, and the part of the gas that is not heated. The results show that up to 240° C., the highest temperature that was employed, the expansion of both argon and helium is very nearly the same as that of air and hydrogen.

December 5, 1895.—"Studies in the Morphology of Spore-producing Members. Part II. Ophioglossaceæ." By F. O. Bower, F.R.S. Preliminary Statement on the Sorus of *Danæa*, by F. O. Bower, F.R.S.

In Part I. of these studies it had been shown on comparative grounds to be probable that septation of sporangia, previously in the race simple, had taken place among the Lycopodineæ. It appeared, however, important to show that such a process of septation has taken place elsewhere; examples of it are found in the anthers of many Angiosperms of the orders Mimoseæ, Onagraceæ, Loranthaceæ, Rhizophoreæ, &c. The development has been studied in certain cases, and it is seen that a partial sterilisation of sporogenous cells results in the formation of sterile septa, which may vary greatly in thickness from a broad band of tissue to a narrow one; sometimes the septum may be represented by a single layer of cells of the nature of a tapetum, or the septum may be incomplete. A comparison of these cases with plants of Pteridophytic affinity shows that similar structural and developmental details are found: the most conspicuous case is that of *Danæa*, in which large synangia are found on the under-surface of the leaf; these, though attached along the leaf surface, have a structural similarity to the spike of *Ophioglossum*. It is not uncommon to find in them, as in the Angiosperms quoted, great variety of size of the loculi, and of thickness of the septa, while incomplete septa are also common: the close parallel as to these characters is a very striking feature, and raises the probability of their having resulted from a similar mode of evolutionary progress, *i.e.* by septation.

The second part of the "studies" refers to the Ophioglossaceæ, and the suggestion made by various writers (Mettenius, Strasburger, Celakovsky, and others), that they are related to the Lycopods is upheld; it is supported on grounds of comparison of external form, of anatomy, of the characters of the Gametophyte and embryology, as far as known. From these various sources a general support of the relationship has been traced, the nearest point of comparison appearing to be between *O. Bergianum*, and *Phylloglossum Drummondii*. It is contended that the external similarity of these plants, long since recognised, is not a case of mere mimicry, but of real relationship, though this probably dates from an unknown common ancestry.

Such a relationship involves the idea of septation; but it has been shown that septation of a very similar nature has taken place in the anthers of Angiosperms. *Danæa* among Pteridophytes shows very similar characters, and, finally, a minute study of development in *Ophioglossum* has elicited facts which are compatible with such a view. From simple types of *Ophioglossum* a progression may be traced to the larger and more complex species, *e.g.*, *O. palmatum*; while a somewhat parallel sequence would lead from such a plant as *Botrychium simplex* onwards to the larger, elaborate species of the genus. *Helminthostachys* appears to hold a somewhat independent position.

December 12, 1895.—"On the Formation and Structure of Dental Enamel." By J. Leon Williams, D.D.S., L.D.S.

The special points in the formation and structure of ename

which I have attempted to elucidate in this paper, may be summarised as follows:—

(1) The existence of a very thin membrane, or a structure of membrane-like appearance, lying between the ameloblasts and the forming enamel, and also between these cells and those of the stratum intermedium. I have also, in many specimens, seen a similar membrane covering the odontoblasts.

(2) The formation of enamel by deposit, and not by cell calcification. This deposit probably consists of two distinct cell products—a granular plasm and spherules of calcoglobulin.

(3) The relation of the cells of the stratum intermedium to true secreting tissue; this relation being especially marked in the enamel organs of the rat and mouse.

(4) An intricate vascular network in the stratum intermedium. I should also mention that I have seen a free distribution of blood vessels in the odontoblastic layer of cells in the mouse, rat, and calf, as well as in human embryos, thus conclusively proving that these cells are not calcified.

(5) The fibrous character of enamel in many of the lower animals, and the change of these fibres into more or less regularly arranged granules in the monkey and in man.

(6) That the varicosities of the enamel rods are not caused by acids (although often rendered more clear to view by acid treatment), but represent a true structural peculiarity of this tissue. That these varicosities, which often continue in an uninterrupted line across large fields of view, correspond with the course of one set of fibres. The varicosities may, therefore, be caused by the presence of this set of cross fibres. The only alternative explanation which has occurred to me is that there may be a rhythmic, simultaneous action of all the ameloblasts concerned in the deposit of the material for enamel building. The last theory seems to be less reasonable than the first.[1]

(7) The Retzius bands are often as distinctly marked in forming as in mature teeth, and in teeth which have been kept constantly moist, as they are in dried specimens. The enamel rods are often seen to pass without break across several of these bands. The bands are principally due to a deposit of pigment, and not to imprisoned air or gas, as claimed by von Ebner.

Chemical Society, December, 5, 1895.—Mr. A. Vernon Harcourt, President, in the chair.—The following papers were read:—Researches on the terpenes, VI. Products of the oxidation of camphene; camphoic acid and its derivatives, by J. E. Marsh and J. A. Gardner. Camphoic acid, $C_{10}H_{14}O_6$, is the chief oxidation product of camphene; a number of new derivatives of the camphopyric acids, $C_9H_{14}O_4$, are described.—New derivatives from α-dibromocamphor, by M. O. Forster. On treating α-dibromocamphor with nitric acid, a lactone, dibromocampholidid, $C_{10}H_{14}Br_2O_2$, is obtained; on reduction it yields an unsaturated acid, bromocamphorenic acid, $C_{10}H_{15}BrO_2$. Camphorenic acid, $C_{10}H_{16}O_2$, and campholidid, $C_{10}H_{16}O_2$, have been prepared.—Isomeric π-bromo-α-nitrocamphors, by A. Lapworth and F. S. Kipping. π-bromo-α-nitrocamphor is obtained, together with a bromocamphoric acid, by heating π-dibromocamphor with nitric acid; it is converted into an isomeride by crystallisation from hydrochloric acid. These two substances are probably cis- and trans-isomerides.—Derivatives of π-bromocamphoric acid, by F. S. Kipping. π-bromocamphoric acid, when treated with alkalis, yields first a lactonic acid, $C_{10}H_{14}O_4$, and then π-hydroxycamphoric acid, $C_{10}H_{16}O_5$; it probably contains the group CH_2Br.—π-dibromocamphoric acid and its derivatives, by F. S. Kipping. π-dibromocamphoric anhydride, $C_{10}H_{12}Br_2O_3$, is prepared by the action of bromine and red phosphorus on π-bromocamphoric acid; it yields π-dibromocamphoric acid, $C_{10}H_{14}Br_2O_4$, when heated with nitric acid, and π-bromocamphanic acid, $C_{10}H_{13}BrO_4$ on boiling with water.—ω-bromocamphoric acid, by F.S. Kipping. ω-bromocamphoric acid, isomeric with π-bromocamphoric acid, is obtained by hydrolysing Wreden's bromocamphoric anhydride.—π-chlorocamphoric acid, by F. S. Kipping and W. J. Pope. π-chlorocamphoric acid, $C_{10}H_{15}ClO_4$, is prepared by oxidising π-dibromocamphor with nitric acid.—Derivatives of α-hydrindone, by C. Revis and F. S. Kipping. Dibromohydrindone is obtained by the action of a soda solution of bromine on α-hydrindone at ordinary temperatures, whilst at 100° a condensation product of the composition $C_{18}H_{12}O_3$ is obtained. When monobromohydrindone is dissolved in cold alcoholic potash, a condensation product of the composition $C_{18}H_{13}BrO_2$ is deposited.—The alkaline reduction of metanitraniline, by R. Meldola and E. R. Andrews. Alkaline reducing agents convert metanitraniline into an azoxy-compound,

$$\begin{matrix} NH_2.C_6H_4.N \\ NH_2.C_6H_4.N \end{matrix}\Big\rangle O;$$

the corresponding azo-compound has also been prepared.—The chemistry of dibromopropylthiocarbimide; and the action of bromine and iodine upon allylthiourea, by A. E. Dixon.

[1] Since the above was written, I have demonstrated that there is a simultaneous deposit of the spherical bodies over the entire surface of forming enamel.—J. L. W.

Linnean Society, December 5, 1895.—C. B. Clarke, F.R.S., President, in the chair.—Messrs. Bernard Arnold and Rupert Vallentin were admitted, and the following were elected Fellows of the Society: W. M. Christy, Rev. H. P. Fitzgerald, A. W. Geffeken, Rev. E. A. Peacock, Rev. T. R. Stebbing, and W. O. Stentiford.—The President called attention to a portrait of the late Prof. Babington, of Cambridge, which had been lately presented by his widow to the Society. On the motion of Dr. Murie, seconded by Mr. A. W. Bennett, a vote of thanks to Mrs. Babington was unanimously accorded.—Prof. Stewart offered some remarks on the types of the axes of certain Gorgonaceæ, in which he referred chiefly to the importance or otherwise of the presence of spicules in the axes, and exhibited the following species in illustration of his remarks: *Paragorgia arborea*, *Melitodes ochracea*, *Suberogorgia suberosa*, *Corallium rubrum*, *Caligorgia verticillata*, *Verrucella guadalupensis*, *Isis hippuris*, *Plexaurella crassa*, and *Eunicella verrucosa*. Some criticism was offered by Dr. Murie, chiefly in relation to the structure of *Gorgonia flabellum* and *Gorgonia setosa*.—Mr. Martin Woodward exhibited and made remarks on a living specimen of *Ouramœba*, which he thought should be regarded as a common Amœba attacked by a parasitic fungus.—Mr. G. C. Druce communicated a paper on a new species of *Bromus* in Britain, which was said to differ from others of the genus in its inflorescence, having single, short, stiff pedicels arising alternately right and left of the main rachis, each bearing at its extremity 3-5 sessile, or in some cases shortly stalked spikelets, giving an interrupted and compact appearance to the whole inflorescence, which is made up of two rows of clustered groups of 3-5 spikelets. This peculiar feature being absent in its nearest allies, the name *interruptus* was proposed to distinguish it; another feature being that the palea was split to the base, and not merely bifid. It appeared to have been described or referred to by Prof. Hackel as *Bromus mollis*, var. *interruptus*, but Mr. Druce considered that it was sufficiently distinct to be entitled to specific rank. He had found it growing abundantly in a field of vetches near Upton, Berkshire, and specimens had been examined from Headington, Oxford, and Dartford, Kent. In a discussion which followed, Dr. O. Stapf reviewed the literature of the subject, and gave reasons for regarding the so-called new species as merely an abnormal growth of *Bromus mollis*. Critical remarks were made also by Mr. H. Groves and Mr. A. B. Rendle, who were inclined to share the opinion of the last speaker.—A paper was then read by Mr. W. F. Kirby, on some new or little-known *Phasmidæ* in the collection of the British Museum, with illustrative specimens.

Mathematical Society, December 12, 1895.—Major P. A. MacMahon, R.A., F.R.S., President, in the chair.—Prof. Hill, F.R.S., gave a sketch of a note on the convergency of series, by Dr. R. Bryant.—Lieut.-Colonel Cunningham, R.E., communicated at some length a paper on the criterion of 2 as a 16^{ic} residue. A discussion followed the reading, in which Messrs. Bickmore, Kempe and the President took part.—Dr. Hobson, F.R.S., read a short note on the distribution of electricity induced on an infinite disc with a circular hole in it, by Mr. H. M. Macdonald.—A paper by Dr. R. Lachlan, on the double foci of a bicircular quartic, and the nodal focal curves of a cyclide, was taken as read.

Zoological Society, December 17, 1895.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Dr. Donaldson Smith offered some remarks on some of the animals observed by him during his recent journey to the Lakes Rudolph and Stephanie, and alluded especially to the species of zebras and antelopes encountered during his journey.—Mr. Sclater exhibited and made remarks on the head of an antelope obtained in Kavirondo, British East Africa, by Mr. E. Gedge. This antelope had been hitherto usually identified with the "kob" of Western Africa, but appeared to belong to a distinct species, to which the name *Cobus thomasi* had been given by Herr Neumann.—Mr. G. F. Hampson read a paper on the classification of two sub-families of the moths and of the family

Pyralidæ, the *Schœnobiinæ* and *Crambinæ*.—A communication was read from Mr. Oldfield Thomas, on *Cœnolestes*, a still-existing survivor of the Epanorthidæ of Ameghino, and the representative of a new family of recent Marsupials.—Mr. Walter E. Collinge read a paper on the sensory and ampullary canals of *Chimæra*, and the innervation of the same.—Mr. F. A. Bather read a paper on the fossil crinoid *Uintacrinus*. The paper attempted a complete morphological description of *Uintacrinus socialis*, based on specimens from the Upper Cretaceous Beds of Western Kansas, now in the British Museum.—A communication from Dr. C. Brunner von Wattenwyl gave a list of the Orthoptera of the Hawaiian islands.

Royal Meteorological Society, December 18, 1895.—Mr. R. Inwards, President, in the chair.—Mr. R. H. Scott, F.R.S., read a paper on some of the differences between fogs, as related to the weather systems which accompany them. In this it was shown that there are at least two distinct classes of phenomena described under the generic name of "fog." In the case of anticyclonic fogs, no rainfall takes place; the temperature is low in the morning, and there is a considerable rise of temperature during the day; while in the case of cyclonic fogs, rainfall does take place, and the temperature is high in the morning, frequently approaching or even equalling the maximum for the day. Mr. Scott also investigated the cases of several well-marked fogs in London, and found that there was no direct relation traceable between the temperature accompanying them and the death rate.—Major H. E. Rawson described the results of his analysis of the Greenwich barometrical observations from 1879 to 1890, with special reference to the declination of the sun and moon.—A paper by Mr. S. C. Knott was read, giving the results of his meteorological observations taken at Mojanga, Madagascar.—Mr. Scott also exhibited some specimens of the illustrations in the "International Cloud Atlas," which is now being prepared for publication.

PARIS.

Academy of Sciences, December 23, 1895.—Annual public meeting.—M. Marey in the chair.—The President delivered an address, in which reference was made to the celebration, in October last, of the centenary of the Institute of France. The members and associates deceased during the year—MM. Pasteur, Verneuil, Larrey, Cayley, Dana, Vogt, Ludwig, Huxley, Lovén, Hellriegel—were referred to, and a brief *résumé* given of the life-work of each. The President then announced that a biennial prize (20,000 fr.), which is in rotation in the gift of each of the five Academies, and which this year fell to the Academy of Sciences, has been awarded to M. Raoult for his discovery of the numerical relations between the molecular weight of a substance and the lowering of the freezing point and vapour pressure of its solvent. The other prizes were awarded as follows: The Francœur prize to M. J. Andrade, the Poncelet prize to M. G. Robin, for his contributions to mathematical physics. In Mechanics, the extraordinary prize of 6000 fr. was divided between M. Mottez (2500 fr.), for his work on the correction of ships' compasses; M. Houette (1500 fr.), for his aids to navigation; M. Gosselin (1500 fr.), for his method of studying the velocity of projectiles; and M. Baucher (500 fr.), for his study of the action of sea-water upon metals. The Montyon prize was given to M. Galliot, for a new application of electric traction on canals; and the Plumey prize to MM. Pollard and Dudebout. The Fourneyron prize was divided between M. G. Marié and M. Lecornu, for their experimental and theoretical work on steam governors. In astronomy, the Lalande prize fell to M. M. Hamy; and the Valz prize to Mr. Denning (of Bristol), for his work on comets and shooting stars. In Physics, M. E. Bouty was accorded the La Caze prize for his numerous researches in electricity and magnetism; in Statistics, the Montyon prize was divided between M. A. Martin and M. C. Baltet, whilst honourable mention was accorded to MM. Hovelacque and Hervé. In Chemistry, the Jecker prize was divided between M. Tanret (6000 fr.), M. Renard (2000 fr.), and M. Burcker (2000 fr.); whilst the La Caze prize was given to M. Le Chatelier for his researches on the combustion of explosive mixtures, pyrometry, and thermodynamics of chemical processes. In Mineralogy and Geology, the Grand prize for the physical sciences was adjudged to M. C. Brongniart for his researches in palæontology; the Delesse prize to M. Delafond for his stratigraphical studies; whilst the Bordin prize is equally divided between M. de Pousargues and M. Barrat. In Botany, the Desmazières prize was awarded to M. Borzi, the Montagne prize to M. F. Renauld, and the De la Fons-Mélicocq prize (900 fr.) to M. G. de la Marlière. In Anatomy and Zoology, the Thore prize fell to M. P. Mégnin, the Savigny prize being not awarded. In Medicine and Surgery, three Montyon prizes were given, to MM. Gangolphe, Imbert, and Teisser; mentions and minor awards went to MM. Chipault, Gouguenheim and Glover, Polaillon, Bellini, and Parant. The Barbier prize was divided between M. Bœckel and M. Dupuy, the Bréant prize being left unawarded. M. E. Reymond was adjudged the Godard prize, M. Lancereaux the Chaussier prize, and M. Vaillard the Bellion prize, with honourable mention to M. Vincent and M. Rouget, M. Mauclaire and M. Detroye. The Mège prize was awarded to M. Baudron, and in connection with the Dusgate prize (not given) honourable mention was accorded to M. Icard. The Lallemand prize was divided between M. Toulouse and M. Halipré, with mention of MM. Chervin and Debierre. In Physiology, the Montyon prize was given to M. Artus (with mention of M. Tissot), the La Caze prize to M. Dastre, the Pourrat prize to M. Charrin, the Philipeaux prize to M. Chabrié, the Martin-Damourette prize being divided between M. Besson and M. Cristiani, with honourable mention of Dr. de Keating Hart. In Physical Geography, the Gay prize was awarded to M. Angot, a second prize (1000 fr.) being given to a paper by an anonymous author. General prizes: The Montyon prize (unhealthy industries) was given to M. Gérardin, the Trémont prize to M. B. Renault, the Gegner prize again to M. Paul Serret, the Petit D'Ormoy prize to M. Albert Ribaucour, for the mathematical sciences, and to M. Pomel for the natural sciences. The Leconte prize was awarded to Lord Rayleigh and Prof. Ramsay for their work on the constitution of atmospheric air. The Tchihatchef prize was adjudged to Dr. Radde, the Gaston Planté prize to MM. J. and P. Curie, the Saintour prize to M. Termier. The Cahours prize was divided between MM. Lebeau, Simon, and Varet, the Alberto Levi prize (50,000 fr.) between MM. Behring and Roux; to the former for his discovery of the antidiphtheric serum, and to the latter for the happy application which he has made in France of this discovery. The Kastner-Boursault prize was awarded to M. Baudot for his improvements in multiplex telegraphy, the Laplace prize to M. Bachellery, and the Felix Rivot prize to MM. Bachellery, de Ruffi de Pontevès Gevaudan, Delemer, and Labordère. Details of the prizes announced for 1896, 1897, 1898, and 1899 are given.

BERLIN.

Meteorological Society, November 5, 1895.—Prof. Hellmann, President, in the chair.—Dr. Zenker gave an abstract of a lengthy paper on the thermal constitution of climates. He explained how, from the solar radiation which he had previously calculated out for the outer boundary of the atmosphere, he had deduced that which takes place at the inner; and how from the latter, taking into account the radiation from the earth, and the existence of clouds, he had determined the annual and monthly temperatures for areas of each two degrees of the earth's surface. In part two of his paper, he had compared the temperatures calculated as above with those actually recorded for many places in India, Africa, America, and Australia.—Mr. Archenhold exhibited the negative of a photograph of a lightning-flash taken on August 24 last. The negative showed one narrow black flash on the dark field of the heavens above the brightly illuminated tree-tops, and a second much broader, bright flash, which was brighter than the tree-tops. The opinion was expressed that probably the great intensity of the possibly multiple flash may have led to the solarisation of its own image.

Physiological Society, November 8, 1895.—Prof. du Bois Reymond, President, in the chair.—Dr. Hausemann spoke on the large interstitial cells of the testis. He had found that they occur somewhat rarely in the connective tissue between the tubules in hibernators during their winter sleep, but are, on the other hand, extremely numerous after they awake. In man they are plentiful in the newly-born and children, less numerous at puberty and during manhood, and increase again largely in numbers in old-age.—Dr. Rawitz had repeated Loeb's experiments on the normal development of exovates, and the remains of impregnated sea-urchin's eggs after treatment with dilute sea-water. In most cases the exovates succumbed as well as the eggs; in only one case had he observed that while the exovate succumbed, the

egg developed into a complete gastrula. From this it appeared that the exit of a portion of the contents of the egg had no influence on the development of the remaining part.—Prof. Zuntz criticised a recent paper by Filehne and Kiouka, in which they attempted to disprove his view that the increased respiratory frequency during muscular exertion is due to the action on the respiratory centre of some product formed during the activity of the muscles. He showed that their objections do not hold good, and that their experiments do not upset his conclusions.

November 29, 1895.—Prof. du Bois Reymond, President, in the chair.—Dr. René du Bois Reymond spoke on the opposition of the thumb, a point on which very scanty and insufficient information is contained in text-books of anatomy. He had studied in detail the theory of saddle-joints, and on the assumption that the movements take place about two axes at right angles to each other and passing through the point of contact of the two bones, he had arrived by construction at a mathematical formula corresponding to the ideal saddle-joint. This formula shows that a certain very limited amount of rotation is possible in this joint. He had further investigated, by the horopter and photographically, the actual movements of the thumb, the hand being firmly fixed, and gave the several phases of the movements which occur in the joint between the metacarpus and trapezium, and between the phalanx and the metacarpus during opposition.—Dr. Schultz demonstrated on the humerus of a duck the connection between the lungs and the bone cavities.

Physical Society, November 15, 1895.—Prof. von Bezold, President, in the chair.—Prof. Warburg gave a short account of experiments, by W. J. Wäggener, on the temperature of the flame of a Bunsen burner. The measurements were made with carefully-tested Le Chatellier's thermo-electric elements. The accuracy of the measurements was further tested in two directions. Firstly, with reference to the effect of high temperature on the E.M.F. of the element, it was found that prolonged heating makes the platino-iridium wire more markedly irregular than it does the platinum; hence the element was exposed to the flame for a short time only. Secondly, with reference to the disturbing effect of heat conduction, it was found with wires of 0·5, 0·2, 0·1 and 0·05 mm. diameter, that when they are coiled up so that they can be almost completely enveloped in the zone of active combustion the three thicker wires recorded the same temperature, whereas, when not so coiled up, the thicker wires gave a lower temperature. The thinnest wire gave the highest values in the outer edge of the flame and in the zone of active combustion, in the inner cone a lower value than that given by the wire of 0·1 mm. The highest temperature recorded was 1704° C. Taking the highest records of the above four wires, and representing them graphically, a curve was obtained which gave the value 1750° C. for a wire of zero thickness, a temperature not much below the melting point of platinum, 1780° C.—Prof. Thiesen spoke on the formulæ which make it possible to obtain a perfect image with a simple lens.

AMSTERDAM.

Royal Academy of Sciences, October 26, 1895.—Prof. Van Sande Bakhuyzen in the chair.—Prof. Martin read a paper on Tertiary fossils from the Philippines. Basing his arguments upon a collection of fossils formed many years ago by Semper in the Philippines, the author showed that in Luzon, in the upper course of the Rio Grande de Cagayan, there appear neo-miocene strata, which must be considered equivalent to the typical neo-miocene of Java. Similar strata are also found in Cebú; moreover, neo-tertiary (miocene or pliocene?) fossils have been brought away by Semper from the hills of Aringay in Luzón, and finally pliocene ones from the Rio Agusan, Mindanáo. In the Philippines there occur tertiary and newer deposits, which correspond to the newer sediments in Java, both as regards the age and the petrographic structure and the fossil fauna of the said strata.—Mr. Jan de Vries presented a paper on a class of complete functions. Let W be a function of γ of the nth degree, then the general formula is determined for a function that satisfies the equation $W_n - \gamma W_{n-1} + W_{n-2} = 0$.—Prof. Kamerlingh Onnes communicated Dr. Zeeman's measurements on absorption of electrical vibrations in electrolytes, undertaken at the suggestion of Prof. Cohn of Strassburg, and carried out in the Leyden laboratory. The (as yet) preliminary results are: (1) the energy of the electric vibrations in pervading an electrolyte diminishes in the logarithmic ratio; (2) if the wave-length is 6·5 m., the energy has decreased to one-third of its original value when the wave has passed through 6·5 c.m. of a solution of common salt, the resistance of which is $3200 \cdot 10^{-10}$ that of mercury.—Prof. Lorentz presented, on behalf of Mr. A. Smits, a paper, entitled "A Description of the Micromanometer." By means of the instrument described, a difference of pressure equal to $\frac{1}{1500}$ m.m. of water or $\frac{1}{20250}$ m.m. of mercury, may, if all precautions possible are taken, be measured under the most favourable conditions.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Gesammelte Abhandlungen über Entwickelungsmechanik der Organismen: Prof. W. Roux, Erster and Zweiter Bands (Leipzig, Engelmann).—Die Mikroskopische Thierwelt des Süsswassers: Dr. F. Blochmann. Abthg. 1. Protozoa (Hamburg, Gräfe).—Fauna der Gaskohle und der Kalksteine der Permformation Böhmens: Dr. A. FOOD AND ITS FUNCTIONS.

Food and its Functions: a Text-book for Students of Cookery. By James Knight, M.A., B.Sc., F.C.S., F.G.S., &c. Pp. viii + 282. (London: Blackie and Son, Ltd., 1895.)

AS a scientific work bearing upon the culinary art, "Food and its Functions," from the pen of Mr. James Knight, of Glasgow, must form a welcome addition to that branch of literature. The work is described as "a text-book for students of cookery," and the author further explains in his preface that it is an expansion of a course of lectures on dietetics, which he was privileged to deliver to the students in training at the Glasgow Schools of Cookery, and that it aims at supplying such students with a complete manual of the theoretical part of their curriculum. Of the scientific soundness and great value of this book to a considerable section of the educated classes there can be no question, but when we consider its merits as a text-book for students of cookery, we are forced to inquire what sort of students? If for such as desire to become teachers of practical cooking, and have therefore to acquire a certain amount of knowledge of the chemistry of the art and the values of foods from a scientific standpoint, then much of Mr. Knight's information and careful reasoning will certainly be useful. Still more valuable should the book be to the nursing sisterhood of the United Kingdom; and to many medical practitioners also, who have to prescribe food as well as medicine for the sick, and might perhaps be a little more closely acquainted with that part of their responsibilities. But to the ordinary learner of the business of a cook, who wants to practise rather than to preach or advise, we much fear that "Food and its Functions" cannot but be too abstruse and overladen with dry scientific details. The theoretical instruction of cookery classes, the students of which are merely seeking to become proficient workwomen, cannot, we think, speaking from experience, be too carefully pruned down, and put into words that can easily be "understanded of the people." A few simple chemical facts in regard to the different culinary processes, a few touching food-stuffs, with a judiciously condensed explanation of the dietary value of the latter, are very desirable, and may be inculcated with some degree of hopefulness. But if the rubicon of moderation be crossed, the teacher's effort is but lost labour. Not one in fifty can really follow or remember it, and the lesson falls verily upon stony ground. For this cause we are constrained to hold in question the advisability of over-instructing the instructors. A little knowledge is a dangerous thing, as we all know, and it is, moreover, a fruitful source of vanity. When the holder of a brand-new diploma—crammed with fine words—proceeds to teach, what a temptation there must be to let some of them loose, especially before an audience unable to detect inaccuracies! But when he or she, veneered with a little anatomical smattering by the aid of Mr. Knight's text-book, proceeds to chalk out on the blackboard diagrams of the alimentary canal, the stomach, the contents of the chest and abdomen, the thoracic duct and lymphatic vessels, with a few words concerning "Bernard's theory of Glycogenesis," and Pavy's view of the same, how learned the board-school-girls, or evening continuation class (who, between ourselves, want to know how to make "toad-in-the-hole") will think her, and how frightened they will be at her awful disclosures as to the secrets of their interior economies! But to be serious, while granting to the full the undoubted importance of Mr. Knight's section on the physiology of digestion to the purely theoretical student, and its value in the hands of the trained nurse, who ought, be it added, to be equally well trained in sick cookery, we cannot admit that it is necessary, or indeed advisable, for ordinary cookery classes; neither can we agree with him when he says that "it is impossible to secure the rational treatment of food without at least a slight acquaintance with" its "subsequent course within the body itself."

Having thus endeavoured to indicate the classes of readers who ought to benefit by Mr. Knight's three scientific sections, and the class for whom we consider them inapplicable, save in so far as a few simple facts to be found in the first two are concerned, we return with no little satisfaction to "parts iv. and v.," in which a goodly store of information is to be found, which ought to be appreciated not only by mere students of cookery, but by every one interested in the question of diet in relation to health, and the still more difficult one of foods best adapted to persons suffering from various forms of illness. In the former section, "Foods in detail," we find explanatory notes as to the chemical properties and dietetic value of dairy produce, eggs, animal food, fish, cereals, legumes, root-vegetables, green-stuff, fungi, fruits, accessories and condiments, beverages, alcoholic drinks, wines, ale and cider, with aërated and mineral waters. The culinary methods which are best suited to many of these, in view to their preparation for food, are adverted to, and the important question of the digestibility of each not lost sight of. The first three lessons in part v., "Dietetics," are of general interest, and ought to be studied by every housewife, for in them will be found the advice, already alluded to, touching dietary scales, diet in relation to infancy, adolescence and age, and referring to food in times of sickness, with special models to meet the cases of standard complaints.

In his last lesson regarding cookery methods, the author certainly betrays a want of practical knowledge. But this, in consideration of the excellence of his scientific instruction, may perhaps be excused. He treats of roasting and boiling with accuracy, but he is hardly correct in advocating broiling by gas *below* the flame in supersession of the time-honoured practice *over* glowing coals. "The value of the grill," says Sir Henry Thompson in allusion to that method, "is nowhere better understood than in England," and we certainly doubt whether any other way of treating a chop or steak will be accepted in the City of London, so celebrated for its grill-rooms. We do not mean to say that meat may not be done in the manner indicated by Mr. Knight, but we maintain that it can never "taste of the fire," to borrow a well-known phrase, as a chop does when well broiled over a clear fire. Nor do we concur with him, Count Rumford's dictum notwithstanding, regarding oven-roasting. Even if every trace of the oven taint be absent, no piece of

meat can be properly and constantly basted by this process, which means that it cannot possess the best qualities produced by proper roasting. The *rôtisseur*, whom Brillat Savarin considered to be like the poet "born not made," was skilful with the spit, and certainly no oven-roasted bird can approach one cooked in that manner. Mr. Knight becomes confused in regard to the frying processes. To dry-fry, the French word *sauter* is alone applicable; to wet-fry, the term is *frire*. By the former, the thing fried is supposed to be tossed or "made to leap," hence *sauter;* by the latter, it is boiled in seething fat or oil—not in a *sauté*-pan, which is too shallow, but in a *friture*-pan or frying-kettle. Clarified beef suet or prime fat is superior to oil for many things; it does not heat so rapidly, nor does it boil over as the latter is prone to do. The object of stewing is not to extract all the nutritive juices of food. On the contrary, in all the best examples of the process, those juices are sealed up to begin with as much as possible, by blanching in the case of white meat, or dry frying (the *faire revenir* of French cookery) in that of brown. After blanching, white meat is refreshed, and then laid on a couch of vegetables covered with broth and very gently stewed; while after having been seized, brown meat is moistened with warm broth just brought to the boil once, and then simmered gently till done. Of braising there are several processes, white meat being done in one way, brown in another. The *faire revenir* process is carried out in regard to the latter, and this is now also done in the case of *bœuf à la mode*—"mettez-la," says Dubois, "dans une braisière ou casserole longue avec du lard fondu; faites-la revenir sur un feu modéré jusqu'à ce qu'elle soit bien saisie et colorée: mouillez alors la viande." Lastly, with reference to soups, we should call a perfect *consommé* the finest rather than the "richest" form of soup; the latter term would be better applied to bisques, thick turtle, and all to which eggs, butter and cream are added. These few slips however are, as we have said, excusable on the part of an author who has given so much valuable information in the major portion of his work. In recommending it to all educated readers who are interested in the subject, we would say to those who may desire to use it in their instruction of the illiterate—do not lose sight of the fact that over-elaboration of the scientific and theoretical aspect of cookery may tend to the somewhat perfunctory teaching of its practical side. For this reason, as far as teaching in board-schools and evening continuation classes is concerned, let sound practical instruction be the main point, with just sufficient of theoretical teaching to explain the scientific reasons which render this, that, and the other step necessary in the different methods of cooking, and why various food-stuffs differ in nourishing value.

THE STUDY OF FUNGI.

Introduction to the Study of Fungi, their Organography, Classification, and Distribution; for the use of Collectors. By M. C. Cooke, M.A., LL.D., A.L.S. Pp. iv.+360. (London: Adam and Charles Black, 1895.)

AS a terminal group, the Fungi possess but little interest for those whose aim is to gain an insight into the general scheme of evolution of the plant-world. On the other hand, it may safely be asserted, without fear of contradiction, that no group of plants has better repaid the investigations of the specialist, as illustrated by the brilliant discoveries of De Bary, Brefeld, Ward, and others. The important part played by parasitic fungi in connection with numerous plant and animal diseases has of late years also attracted considerable attention, and with the exception of Great Britain, almost every civilised country in the world has one or more institutions specially devoted to the investigation of this branch of the subject. Another branch of the study deals with the classification or systematic arrangement of fungi, the importance of which can only be realised when it is known that above forty thousand described species have to be dealt with in such a manner that their specific individuality, affinities, location in the scheme of classification, and distribution, may be easily accessible to workers in other branches of the study. In the work under consideration, the author has given the amount of morphological information he considers necessary for the systematist to possess, at the same time indicating the additions to our knowledge resulting from the investigation of the life-history of individual species; but it is in the sections devoted to classification and distribution that Dr. Cooke appears at his best, and here we find embodied the matured experience gained during the author's connection with Kew, where he had charge of the unrivalled collection of fungi, with its thousands of type specimens, in addition to the opportunities of examining numerous collections, received at different periods, from every quarter of the globe. In the chapter on classification, Brefeld's researches are analysed, and his proposed system of classification given in a tabular form. Saccardo's arrangement of the fungi is also thoroughly explained and criticised, as "it will doubtless come into universal use where expedients are valued rather for their utility than their consistency." The above quotation refers to the elevation of the Friesian sub-genera of the Agaricini to generic rank by Saccardo; and, while admitting that there is an apparent trifling with a preconceived conception of generic value in elevating to the same level, the sub-genera and genera of the same author, more especially when the genera are so broad, as in the Friesian system; yet perhaps in these days utility is of more value than consistency in a purely systematic work, the real value of which depends on the ease with which the organisms of which it treats can be recognised, and this can usually be more readily accomplished by the use of artificial methods than by adhering strictly to a supposed uniform standard of relationship, at all events so far as species and genera are concerned.

The author advocates the continued use of the term *spore* for the reproductive body of the Basidiomycetes, and *sporidium* for that of the Ascomycetes; with this we cannot agree, considering *basidiospore* for the former, and *ascospore* for the latter as conveying more definite information, and further, freeing the subject from the very vague term spore.

We cannot accept either of the following statements, which certainly should be qualified in a future edition of the book. "Of the 9600 known species of Hymenomycetal Fungi, really parasitic species are almost, if not wholly unknown." "All the parasites on living leaves

which are not of insect origin, are Fungi." *Agaricus melleus* and many species of *Polyporus* are too well known as parasites, and in the tropics coriaceous leaves of evergreen plants are victims to the attacks of parasitic lichens and algæ; lichens are mentioned, as the author holds to his previous view, that these are entirely distinct from fungi, giving a summary of his views on this subject.

We should look elsewhere in vain for anything approaching the amount of information contained in the section devoted to the geographical distribution of fungi, a chapter which indicates not only what has been done, but also what remains to be done.

A noteworthy feature of the book is the full bibliography given at the end of each chapter, treating of the special subject dealt with. There is also a glossary explaining the scientific terms adopted. The index might with advantage have been fuller. The numerous illustrations have in most instances done service before, but nevertheless serve to elucidate the text; and on the whole it may be said that no one aspiring to the study of fungi from the systematic standpoint, can afford to ignore the present work.

GEO. MASSEE.

OUR BOOK SHELF.

Rambles in Japan, the Land of the Rising Sun. By H. B. Tristram, D.D., LL.D., F.R.S. With forty-five illustrations by Edward Whymper, from sketches and photographs. (London: The Religious Tract Society, 1895.)

CANON TRISTRAM has done well in putting together this record of a visit to Japan, which, although not "recent" when measured by the rapidity of the present march of Japanese history, occurred only a few years ago. The object of the visit was mainly to study the working of Christian missions on the spot; and this is a welcome fact, because it ensures an audience for what the author has to say, who cannot but profit greatly from the acute observations and calm judgments which he records. While making no pretensions to scientific treatment, Canon Tristram's book is to the average run of tourist twaddle on Japan, as a good novel is to a "penny dreadful." It is truthful, well-written, and inspires confidence. Under the guidance of his daughter, who as a missionary had acquired the Japanese language, Dr. Tristram visited some parts of the islands remote from the tourist-track, although all well-known to European residents in Japan. His instincts as a field-naturalist kept him on the alert for all that was to be seen of animal and plant life; and although we fear the precipitancy with which he yielded to temptation in the matter of ivory-carvings and rare china, must have told on his natural history collections, he seems to have brought back a good many plants, insects and birds.

A great number of interesting facts and phenomena are touched upon. The wonderful results of fancy gardening in Tokyo in dwarfing and grafting, seem to culminate in a maple-tree with seven large branches, the foliage of each having a different tint, varying from copper-colour to greenish-white. The art of the Japanese in domesticating such sensitive birds as robins, titmice and warblers, is cited as an instance of the great sympathy for nature which distinguishes the Japanese. Dr. Tristram found that the localities of many of the birds, brought to the seaports for sale, were wrongly described on the labels which were affixed in Europe, and he instances one case in which a species found only in the forests of Nikko, from 3000 to 8000 feet above the sea, had its habitat given as Yokohama. The author is inclined to rank Fujisan second in beauty to the Peak of Tenerife, and he remarks that no Japanese artist would think of painting this much-portrayed mountain from nature, but always from the paintings of the "old masters" of Japanese art. Richly wooded as Japan is, the universality of the use of charcoal as a domestic fuel has necessitated special forest-legislation, based on the strict system of re-planting practised in Germany. Although Dr. Tristram necessarily depended much on second-hand information, he avoids the familiar pitfalls of the uneducated writer, and but for a printer's error in the population of Nagoya, there seems little wanting in the way of accuracy.

The illustrations add greatly to the interest of the book; but while all of them are worthy of the name they bear, it is almost with a feeling of shock that one reads "Whymper" on several ordinary half-tone process blocks.

A Manual of Botany. By Prof. J. Reynolds Green, F.R.S., Sc.D., F.L.S. Vol. I. Morphology and Anatomy. Pp. x + 398. (London: J. and A. Churchill, 1895.)

PROF. GREEN has set himself a difficult task in attempting to put new wine into old bottles. Bentley's book, on which the present work is based, was admirable in its time, but to-day it strikes one as being somewhat inflexible both in style and ideas. It is true that in the volume before us there is a great deal of very useful information, which is put better and more clearly than elsewhere; in fact some of the subjects are so well treated, that we cannot help regretting that Prof. Green did not see his way to give us an altogether original work.

We notice, however, with regret, that the morphology of the inflorescence is here somewhat hazy, and it seems a pity that Eichler and Gray were not more closely followed, since their views, especially those advanced by the former, are certainly the most philosophical, as well as the most lucid and comprehensive of any which have as yet been put forward. The treatment accorded to the stele does not strike us very favourably; the student may be well forgiven if he abandons all attempts to understand the complex and apparently irreconcilable ideas embodied in the expressions "monostely" and "polystely" respectively.

The position of the axis should have been marked in the floral diagrams, as without it, one fails to recognise the correct orientation of the parts of the flower. This need is the more obvious in cases where the actual position of the axis varies in figures on the same page, as in Figs. 248 and 250, in which it falls above and at the side respectively.

But notwithstanding these faults, the book provides, on the whole, a clear and comprehensive account of the structure of plants.

Rope Driving. By John F. Flather, Ph.B., M.M.E. Pp. 230, and figs. 92. (New York: John Wiley and Sons. London: Chapman and Hall, Limited, 1895.)

THIS is a handy little book on the transmission of power by means of rope gearing; it contains a large amount of sound information on the various arrangements of driving gear, and their design, the best speeds at which ropes should be run, and the tension to which they should be exposed. The reasons of decay and means of preservation of ropes are succinctly dealt with; as also are the relative advantages of cotton and manilla hemp ropes when worked under different conditions. The book is certainly worthy of a place in any technical library, as the subject is one which is daily engaging increased attention, affecting as it does the efficient driving of mills, factories, and electric installations, and the transmission of motive power to places more or less isolated from its source.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Cause of an Ice Age.

SEVERAL letters from Sir Henry Howorth, Dr. Hobson, Mr. Culverwell, and Prof. Darwin, having appeared in NATURE relating to my little book on the "Cause of an Ice Age," I shall be glad if you will allow me to make a few remarks on the matter. In his first letter, Sir Henry Howorth thinks I have omitted to give Wiener the credit which was justly his due. Subsequent letters by Dr. Hobson and Sir Henry Howorth may be held to have cleared up this matter; still there is a point which has escaped Sir Henry Howorth's attention, and I therefore refer to it again.

The facts are as follows. When I first began to work at the Ice Age I arrived independently, as any mathematician might easily have done, at a theorem by no means difficult, which seemed to me of importance in connection with the subject of geological climates. I had never seen this theorem before; had I done so I should, of course, have properly acknowledged its prior discovery.

Soon after the publication of my book, Prof. Darwin kindly pointed out to me that the mathematical theorem in question had been already given by Wiener. Thereupon I did all that it seemed possible to do. I called attention to Wiener's priority at once by a letter to NATURE, which appeared on February 18, 1892, and I also mentioned his priority both in the preface and the text of the second edition of the "Cause of an Ice Age," which was published in 1892. Sir Henry Howorth, when he wrote his recent letters in which he thought I had not rendered justice to Wiener, could not, I am sure, have known all the facts as above stated.

Mr. Culverwell thinks that I was wrong in attributing a certain opinion to Croll, and I quite admit that this charge might once have been correct. The fact is, I had been mistaken in the meaning I read into a passage in Croll's "Climate and Time," p. 56. But I think if Mr. Culverwell had known the circumstances, he would hardly have considered it necessary to raise this question again. On the appearance of the first edition of my book, the mistake I had made was kindly pointed out by Mr Monck, as well as by Mr. Noble, and I think by others; and I accordingly amended the second edition. In the *Geological Magazine* for February 1895, p 58, Mr. Culverwell appeals to me to correct certain passages relating to this point which he puts into italics from the first edition. My excellent friend had not the slightest notion that these passages had been already corrected in the second edition, published two years before his paper.

I must, however, say that on looking over my book again in connection with this correspondence, I consider that some of the references I have made to this particular point might be further amended. If, however, Sir Henry Howorth still thinks that I have at any time regarded Croll's work otherwise than with due respect, I would like to remind him of the words in both editions, p. 112, in which I said:—

"I was greatly struck by this work ('Climate and Time') when I first read it many years ago. Subsequent acquaintance with this volume, and also with his second work ('Climate and Cosmology'), has only increased my respect for the author's scientific sagacity, and my admiration for the patience and the skill with which he has collected and marshalled the evidence for the theory that he has urged so forcibly."

I have studied with much interest and profit the investigations made by Mr. Culverwell in connection with the astronomical theory of the Ice Age, and I may be permitted to say how glad I am that so excellent a mathematician and physicist should have had his attention drawn to this subject. I may, however, take this opportunity to explain why I have had to remain unconverted by certain of his arguments, notwithstanding that they have carried conviction to Sir Henry Howorth and Prof. Darwin.

In his earlier paper in the *Geological Magazine* for January 1895, p. 9, Mr. Culverwell has demonstrated that the direct sun-heat received on any parallel at the time of greatest eccentricity, is the same as that now received on the parallel not more than three or four degrees north. This seems to me not only a novel, but also a very instructive result, and is in any case a valuable contribution to the theory. Mr. Culverwell, however, goes on to deduce from this that the climatic change in England between the present time and the time of the greatest eccentricity, would be no greater than the present climatic difference between Yorkshire and Cornwall, and hence he concludes that the astronomical theory is incompetent to account for the Ice Age. Prof. Darwin seems to think that this argument is unanswerable; I hope he will forgive me if I say that here my dissent begins. I think the facts cited do not warrant the inference which Mr. Culverwell would draw from them. With due respect to Mr. Culverwell, I would say that he seems at this point to have quite forgotten that the actual temperature in a region depends not merely upon the sun-heat there received, but also upon the transference of heat across the boundaries of that region. He takes the actual temperatures of Yorkshire and Cornwall; but what his argument would really require is a totally different thing. It would be the temperatures of those counties if each of them were perennially surrounded by a wall extending to the top of the atmosphere, and adiabatic to all heat except direct solar radiation.

This point is so important that I must put it in a somewhat different manner. It is certain that the actual climatic gradient from the equator to the pole is very different from what that gradient would have been if each parallel of latitude had marked the course of an adiabatic barricade such that no heat transference *via* earth, air or water could take place from zone to zone. In the latter case I quite admit that the mean temperature due to the sun-heat received on any zone would be actually the mean temperature of that zone, but the same is not true of the actual climatic gradient as we have it in nature For, on account of heat transference, the mean temperature of a zone is by no means the same thing as the mean temperature due to the sunbeams received by that zone.

May I say that I think the fallacy throughout this part of Mr. Culverwell's argument arises from his overlooking the distinction between the actual gradient and the adiabatic gradient. There may be but little difference between the mean temperatures of a zone through Yorkshire, and a zone through Cornwall; but this does not prove, as Mr. Culverwell's theory requires, that there would be but little difference between a mean temperature due solely to the direct sun-heat falling on the zone through Yorkshire, and a mean temperature due solely to the direct sun-heat falling on the zone through Cornwall. This inference would only be sound if all parallels were adiabatic. This they certainly are not.

I do not question that the difference between present temperatures and the temperatures at the time of highest eccentricity might be fairly represented by the difference between the temperature due to the sun-heat received in the latitude of Yorkshire, and the sun-heat received in the latitude of Cornwall. What I do question are the grounds on which Mr. Culverwell maintains that this latter difference (and therefore the former one) is so insignificant as to discredit the astronomical theory of the Ice Age.

I have thus explained in what respect Mr. Culverwell's investigation involves assumptions which are in my opinion unsound. I am accordingly to this extent unable to accept the conclusions at which he has arrived. ROBERT S. BALL.

Observatory, Cambridge, January 2.

THE letter of Prof. G. H. Darwin in your last issue states very clearly the argument on which Mr. Culverwell and himself rely as affording a demonstration of the inadequacy of the astronomical theory. It now seems opportune, therefore, to lay before your readers the general considerations which lead me to the conclusion that the whole argument they rest upon is unsound; and, further, that Sir Robert Ball's ratio of 63 to 37, representing the ratios of sun-heat received by each hemisphere in summer and winter respectively, is (contrary to Prof. Darwin's view) an important factor in any adequate discussion of the problem.

Accepting Prof. Darwin's estimate that the difference in the amount of sun-heat received in our latitudes during high and low eccentricity, would only give to Yorkshire the amount received by London or *vice versa*, I entirely demur to his statement that this would be also a measure of the amount of change in the climates of these places To do so is to assume that the climate of a place, as regards the amount and distribution

of its temperature, is determined by one factor only—the amount of sun-heat it receives.

How very erroneous is this assumption, may be shown by the contrasted climates of places on the east and west sides of the Atlantic, due to the influence of both ocean-currents and prevalent winds; but even more strikingly by a comparison (which I made in my "Tropical Nature") between certain tropical and temperate climates. In Java, about 8° south of the equator, the altitude of the noonday sun in June is about 58½°, while at London during the same month it is 62°, the length of the day at the same time being 5½ hours greater with us. The sun-heat received in London must therefore be *considerably greater* than that received in Java, and, according to the rule that the *amount* of sun-heat determines temperature, London should then have the warmest climate. The fact, however, is that our mean temperature in June is more than 20° lower than that of Java and our mean highest temperature about 18° lower, a result due, as I have shown, to a variety of causes, of which the temperature of the atmosphere in all surrounding areas, the action of aqueous vapour in reducing the loss by radiation, and the accumulation of heat in the soil, are probably the most important. These facts prove, I think, that the amount of heat received by the whole hemisphere, through its influence on both oceanic and aerial currents, must be taken account of in estimating temperatures under different phases of eccentricity; and that any determination of the amounts of sun-heat received at particular latitudes, considered by themselves, are necessarily misleading and must usually indicate a difference of climate far below the truth.

But there is another consideration of even more importance which entirely invalidates the arguments of those who, like Mr. Culverwell and Prof. Darwin, treat the problem as one to be determined by a simple mathematical calculation of amounts of sun-heat received on the same area at different times. This is, the remarkable difference in the behaviour of air and liquid water on the one hand and snow and ice on the other, as regards climate; the former from their great mobility tending to the diffusion of heat, the latter by its comparative immobility to the accumulation and perpetuation of cold. Without this power of accumulation perpetual snow on tropical and temperate mountains, and glaciers in hot sub-alpine valleys and at only 705 feet above the sea-level in latitude 43° 35′ south in New Zealand, would be impossible. In either of these cases, if an elevation of about a thousand feet should double the area of the snow fields, which might easily be the case, the outflowing glaciers would be greatly increased in magnitude and might either descend to much lower levels or spread out over large areas of the lowlands—and all this without any change whatever in the total amount of sun-heat received by the countries in which they occur.[1]

For some years past there has been a persistent attack by astronomers and physicists on the explanation of the glacial epoch put forth by Croll and adopted with some modifications by many students of glacial phenomena. But as these writers have all treated the problem as a question of the direct effect of the amount of sun-heat received at different epochs in corresponding latitudes, completely ignoring the great distributing and accumulating agencies which are always and everywhere in action, their theoretical conclusions appear to us to be entirely beside the question. We have to deal with a highly complicated problem in physical meteorology, which cannot be solved by an appeal to the well-known facts of the amounts of sun-heat received, any more than can the June climates of London and Batavia or the general climates of Ireland and Manitoba or Terra-del-Fuego (in about the same latitude) be explained from similar data. The great merit of Croll was, that he fully realised the complexity of the problem; that he took account of the various relations and reactions of the oceanic and aerial currents, and the physical characteristics of air and water, snow and ice; and that he showed how these causes reacted on each other so that the winds and ocean currents of one hemisphere might have an influence on the accumulation of snow and ice in the other. Whatever errors he may have made in matters of detail, his method was undoubtedly a sound one, and it is because so many recent writers on the subject have wholly ignored his method without even attempting to prove that it is erroneous, that their views appear to us to be both retrograde and scientifically unsound.

ALFRED R. WALLACE.

[1] This remarkable property and its effects are explained in some detail in my "Island Life," p. 131 (second edition), under the heading "Properties of Air and Water, Snow and Ice, in Relation to Climate," and in the four following sections.

The Dying out of Naturalists.

THE dying out of the distinguished school of "naturalists" which this country once produced, and which culminated in Darwin, is a fact which scarcely admits of dispute. I am informed on good authority that it has not escaped the notice of the French scientific world.

I drew attention to it in the address which I delivered to the new Botanical Section of the British Association at Ipswich. I rather described the phenomenon than attempted to explain its causes. But what I said has brought me many interesting communications. It has been suggested to me that as far as botany is concerned, I have much myself to be responsible for. It may be so. But this I may say, that in entering the laboratory I did so with the natural history spirit. I only looked at interesting things with a closer vision. So, if I may go to the other end of the scale, did Darwin when he made use of all the newer appliances of biological research in his later work.

Nothing, it seems to me, is more difficult than to trace to their right causes the springs of human endeavour. Its results are familiar to us, because we live amongst them. We are so prone to assume "motives" off-hand for any human action that we see about us, that nothing seems easier than to explain any new departure that comes in our way. But the process is almost certainly superficial, and the real causes of a social change which breaks upon us suddenly have in all probability been of slow growth, and do not at the moment either reveal themselves or readily lend themselves to analysis.

A friend, a well-known naturalist, gives me his explanation. I suppress his name, as I have not his permission to quote it; but I think what he says is worth printing, as affording ground for reflection. Whether the cause he assigns is or is not well founded, I confess I do not know.

But generalising from experience I can say this: all distinguished naturalists whom I have known have gone ahead in defiance of any and every obstacle. Looking back upon their lives, it was as if fate had conditioned them. It was once said to me that if one ever came across a possible artist of merit, the right thing to do would be to offer him every discouragement. If he had real genius he would transcend his ordeals; if he had not, the world would not be appreciably the poorer if he was quenched.

But I must discriminate. English naturalists of the generation which is now passing away have belonged to two groups. Some have been born to wealth, some to poverty. Class prejudice was against the one; means of livelihood against the other. The richer disciples of our art seem now to have gone irretrievably, and to have no successors. The poorer have changed their tone; they tend to treat science as a career like the Civil Service. They approach those who have any hand in the matter in an extremely business-like spirit. I do not blame them. But this is not the *métier* of the scientific hero. Nor in their memory shall we assemble to found a national memorial or raise a statue.

What is the force that now-a-days quenches the old enthusiasm? My correspondent says that it is the schools, and here is his story. I believe that, at any rate, what he says is the outcome of sincere conviction, or I would not publish it.

"I am pleased to see your remarks upon the dying out of the study of systematic botany, and I see in other papers, too, attention called to this and the diminution of field naturalists. One starts one's natural history usually on these lines when a boy—or, rather, used to—but I noticed things had altered much when I visited my old school last winter. In my day we had lots of naturalist boys; we knew all the localities for insects, plants, shells, &c. Now hardly any one knows anything of the country beyond the playing fields. The 'skipper field,' famous for skipper butterflies; the heath, with its localities for all kinds of insects and plants, are absolutely unknown. The great object of education appears to be to have every boy competing for something absolutely useless to him in later life. They were practising cricket or other games, or cramming for exams. all the while. This remarkable system begins, the masters of this and other schools told me, at about eight years old. There is no time to learn to think or observe. The boys must beat some other school in tennis or football, or must beat some one else in the history of the Punic Wars. Science was taught, but much in the same way. They were neither taught, nor did they get a chance of teaching themselves, any natural history. What the result of this will be it is difficult to foresee, but it certainly accounts a good deal for the diminution in systematists and field-naturalists."

Pendulum Observations in the Northern and Southern Hemispheres.

THE figure of the earth has been determined by three independent methods of investigation. (1) By abstract mathematical calculation of the form which such a body as the earth, rotating as it does, would assume when plastic. (2) By careful measurements of arcs on meridian lines in different latitudes. (3) By pendulum experiments, which have indicated a gradual increase of the force of gravity from the equator towards the poles.

These three methods, after necessary corrections have been applied, correspond so nearly in their results that probably we have ascertained the true ellipticity of our earth as nearly as is possible considering the irregularities of its surface. But there is one point in connection with pendulum experiments which, although it cannot have escaped notice, has not been treated of, as far as I am aware, in any work on astronomy or geodesy, viz. that all the pendulum experiments hitherto made in the southern hemisphere indicate that the force of the earth's attraction is less in that hemisphere than in the northern. The great navigator, Captain Cook, was the first, I believe, to notice this phenomenon in connection with an excellent pendulum clock which he carried with him. He noticed that this clock always went slower at places in the southern hemisphere than it did in the northern hemisphere; but he did not pursue the question.

In November 1893, Dr. John Murray read a paper on Antarctic research before the Royal Geographical Society, and in the appendix to that paper is a communication from Dr. Neumayer, of the Hamburgh Naval Observatory, giving a table of the results of pendulum experiments hitherto made in the southern hemisphere. In the annexed table I have made use of Dr. Neumayer's collected information, reducing his values of the length of pendulum beating seconds, given in metres, to the corresponding values of the accelerating force of gravity in foot seconds, and I have added, from other sources available to me here, the corresponding values of *g* at places in nearly similar north latitudes. By comparison it will be seen that the force of gravity in the northern hemisphere exceeds that in the southern hemisphere, in latitudes between 38° and 62°, by a mean of about ·010. In Dr. Neumayer's table, experiments in the southern hemisphere are recorded as far as lat. 33° 2′ 5″ S. (Valparaiso), but I have not been able to obtain here any records in similar latitudes in the northern hemisphere. In the northern hemisphere experiments have been made at Hammerfest 70° 40′ north latitude, and at Spitzbergen 79° 49′ 54″ north latitude; but no corresponding experiments have yet been made in Antarctic regions.

Taking, however, the values of *g* at Edinburgh and at Cape Horn, in very nearly the same latitudes, 55° north and south, viz. 32·204 and 32·194, and assuming that these values will not vary greatly in their difference at the poles; by a simple calculation we find that the centre of gravity of the earth is approximately $\frac{1}{10}$ths of a mile north of the plane of the equator. It would appear from this that in astronomical observations depending on zenith distances, and consequently on the direction of the plumb-line, not only must corrections be made for the ellipticity of the earth, but also for the true position of the centre of gravity of the earth, which at the equator must deflect the plumb-line about 15″ from the true vertical.

It is a deeply interesting question whether astronomical observations can be, or have been, made to verify the results obtained by the pendulum.

Geographically it is a subject which may approximately be investigated by comparing the masses of dry land now standing above the sea-level in the northern and southern hemispheres; the excess of dry land in the northern hemisphere, at present, being the probable cause of shift of the centre of gravity of the earth northwards.

In mathematical astronomy it presents an extremely difficult but highly important problem, viz. what effect this position of the centre of gravity of the earth has upon the gyratory motion, producing the precession of the equinoxes, which is caused by the attractions of the sun and moon on the equatorial protuberance.

If, as seems probable, a shift in the position of the centre of gravity of the earth north or south of the plane of the equator must produce a shift also in the direction of the axis of gyration, many perplexing geological problems as to varying climates in the same part of the world during different epochs in the world's past history would be at least partially elucidated. There is ample evidence of very widely-extended earth movements of elevation and depression in the past; these must have varied the balance of the earth, and if a change in the balance produces also a change in the direction of the axis of gyration, a change in climate follows as a matter of course.

It is a problem requiring mathematical genius and skill of the highest order for its solution; but it can be hardly denied that it is of very great scientific interest that it should be correctly solved.

Finally, I would wish to draw attention to the importance of accurate pendulum experiments being made in the highest southern latitudes attainable by the Antarctic research parties which are either now being organised, or will, it is hoped, eventually be despatched by the British Government.

Place.	N. lat.	Value of *g*. ft.sec.	Diff.	Value of *g*.ft. sec.	S. lat.	Place.
Washington, U.S.A.	38° 54′	32·1558	·013	32·142	37° 49′ 9″	Melbourne.
Paris	48° 50′	32·183	·009	32·174	49° 8′ 9″	Kerguelen Island.
			·011	32·182	51° 31′ 7″	Falkland Is. No. 1.
				32·178	51° 35′ 3″	Falkland Is. No. 2.
Greenwich ...	51° 29′	32·191		32·180		Mean of Nos. 1 and 2.
Belfast ...	54° 36′	32·199	·008	32·191	54° 31′	S. Georgia
Edinburgh ...	55° 27′	32·204	·010	32·1936	55° 51′ 3″	Cape Horn.
N. Shetlands	60° 45′	32·217				
Interpolated ... (at the rate of ·00275 per degree)	62° 45′	32·222	·010	32·212	62° 56′ 2″	S. Shetlands.

N.B.—The difference in the values of *g* between Washington and Melbourne, if corrected for difference in latitude, would become ·011. Similarly that between Paris and Kerguelen Island would become ·010. The variation in the difference at 54°.$\frac{31}{36}$ south and north latitudes may be due to some local attraction or some inaccuracy in observation.

Wellington, New Zealand, November 12, 1895. H. S. SCHAW.

The Metric System.

IT may not be within the recollection of your readers, and very unlikely to be so in that of the British public, that so far back as 1870–71 the Government of India, in the Governor-General's Council, passed an Act to introduce the metric system into the British dominions in India. However, as all Acts passed by that Government and its Council require the prior sanction of the Secretary of State for India in Council, the measure failed to take its place on the Statute Book of the Empire. His Grace the Duke of Argyle was at that time at the India Office, and it is a matter for much regret that he did not see fit to approve of the measure. That the Government of India did not expect that the Act would be vetoed, is proved by the fact of its having adopted the system in the State Railway Branch of the Public Works Department, then but recently formed. Sir Guildford Molesworth, K.C.I.E., then Consulting Engineer to the Government of India for Railways, published a series of type drawings dimensioned in the metric system. The Government further adopted the metre as the gauge of the narrow-gauge system then introduced for the first time by them. All the platform and other weighing machines sent out were so arranged as to weigh in kilogrammes, tons, and maunds. Had the wise policy of the late Lord Mayo been then approved of, the English commercial and scientific public would not now be clamouring for its adoption in the mother-country, as its great advantages would be patent to all.

In Ceylon the decimal system has been applied to the rupee, and I have not heard any complaints of inconvenience having arisen from such adoption.

Cannot a further agitation be started, to move the Government of England to take steps in the coming session to make a start, at least, in the matter? It might be notified that, for all Government contracts, no other system would be entertained after January 1, 1898. This in itself would give a huge impetus to the movement. F G. BROOK-FOX.

West Kensington, W., December 26, 1895.

The Habits of the Cuckoo.

IN connection with the interesting article in NATURE of Dec. 26, 1895, on the habits of the common cuckoo, it may be of interest to some of your readers to record the following observations, which afford further evidence in support of the contention that the cuckoo occasionally lays its egg before carrying it to the nest in which it is to be deposited.

A few seasons ago, a pair of robins built in the ivy covering the walls of our house. It was cunningly concealed, about five feet from the ground, in a hollow formed between the wall and the interlacing stems of the ivy. The nest was successfully finished, and four or five eggs were laid. One day, in the early hours of the afternoon, the loud notes of a female cuckoo attracted our attention. Almost immediately afterwards we saw the bird on one of the branches of a large yew-tree growing close to the corner of the house where the nest, was placed, and one of our party exclaimed, "Oh! it is holding something in its beak." It seemed in no way disturbed by the close proximity of the house and its inhabitants, and, after a moment's pause, flew down and disappeared behind the angle of the wall. It then quickly reappeared and flew away, making a considerable noise. We immediately went to the nest, and found the cuckoo's egg together with the robin's. The entrance to the robin's nest, and the entire hollow where it lay, was far too small to admit so large a bird as the cuckoo; the short time, also, that the bird was there, presumably points to the fact that it carried its egg thither and simply placed it in the nest.

Some years before, much the same thing occurred in the same garden. In this instance the robin's nest was in a hole in a bank, which was also too small to easily admit the cuckoo. The parent robins were seen furiously attacking the larger bird, who was forced to beat a retreat. But it had already deposited its egg in the robin's nest, where we found it immediately afterwards.

London, December 29, 1895. ANNIE LEY.

A Luminous Centipede.

WAS not the insect seen by Miss Rose Haig Thomas (see NATURE, p. 131) a specimen of the Myriapod *Scolopendra electrica*, or *Geophilus electricus*, a well-known luminous insect whose light is but rarely seen owing to the insect living underground and in manure heaps? It is, however, the only luminous British species. I have but once seen one crawling abroad at night, but I know the insect well. It may be readily captured in the daytime. The light is bright and the colour is the same as that of the glow-worm. According to my observation both sexes are luminous, and the light is not peculiar to the summer season, as is that of the British glow-worm, hence the meeting of the sexes can scarcely be the object of the luminous prevision.

Worcester, December 20, 1895. J. LLOYD BOZWARD.

IT is impossible to give an unqualified reply in the negative to Mr. Lloyd Bozward's question; but for reasons stated in the note appended to Miss Rose Haig Thomas's communication, I see no grounds for doubting that the specimen she observed was an example of *Linotænia crassipes*, and not of *Geophilus electricus* (= *Scolopendra electrica*, Linn.). So far as my experience goes, the latter is very scarce in the south of England. It must be borne in mind, however, that there is no safety in the assumption that every luminous centipede found in this country is certainly referable either to one or the other of these two species. As a matter of fact, the family *Geophilidæ* is represented in England by at least a dozen species, belonging to five genera, and it is possible that all of them possess the property of phosphorescence. Perhaps it is not surprising that persons unacquainted with these facts jump to the conclusion that every luminous centipede they see must be co-specific with the one to which Linnæus gave the name *electricus*. This is so far from being the case, that not one of the many specimens that have been brought of late years to the British Museum, on account of its luminosity, has proved to be an example of this species. No doubt, however, there is much that might be learnt on this subject by the careful preservation of specimens, with particulars as to date, locality, &c., and I need hardly add that I shall be very pleased to identify any examples that are sent or brought to me at the British Museum for that purpose.

British Museum, Cromwell Road, S.W. R. I. POCOCK.

A Lecture Experiment on the Nodes of a Bell.

THE following modification of Chladni's method makes an interesting lecture experiment, and shows the nodal lines of a bell far more sharply and easily than any process already described of which I am aware. For the bell, use a cylindrical glass crystallising pan (say nine or ten inches diameter and four to six inches deep, but almost any size will do), and stand it, rim upwards, on three india-rubber corks. Some light-coloured powder, such as flowers of sulphur, is mixed with soapy water and smeared over the concave surface. The mixture should be quite watery, and can be applied by pouring a little into the bell, which is then tilted as much as possible and rotated round its axis. With one hand inside the bell, press it down firmly on the corks, and excite the rim with a bow. It is best to make double contact with the bow at two opposite points on the rim, and a succession of rapid strokes will produce strong vibrations, the powder meanwhile shooting upwards in arch-like curves, till it collects in four or six distinct vertical lines, easily visible at a distance if held against something black. Using a smaller vessel, smeared only half-way round, no doubt the whole process could be optically projected. G. OSBORN.

The Leys School. Cambridge.

The Critical Temperature of Hydrogen.

IF my allusion to the absence of "fresh experiments" in Dr. Natanson's work is not sufficient acknowledgment of its purely theoretical nature, a reference to my original abstract in the Physical Society's *Proceedings* will, I feel sure, correct any false impression that has arisen in the author's mind on that point. My note was in no way intended as a criticism or expression of opinion. But the Cracow *Bulletin* paper was certainly calculated to give any reader the idea that Dr. Natanson was the only worker besides Olszewski who had attempted to calculate the critical temperature of hydrogen, and, to prevent misunderstanding, a reference to Wroblewski's previous work seemed desirable. As Dr. Natanson still appears to pass over the long and laborious experiments on which the latter investigation was based, and to be unaware that the whole object was to get the critical constants, &c., *from the application of Van der Waals' theory* (which had previously given chemists an accurate knowledge of such data in the case of oxygen, nitrogen, and marsh-gas *before the gases had been actually liquefied*), I must refer *him* to Wroblewski's memoir. Further, it might interest him to consult a paper by Prof. Dewar in the *Philosophical Magazine* for September, 1884, which discusses the critical constants of hydrogen based on the experimental facts known at that time.

G. H. BRYAN.

THE SPERM WHALE AND ITS FOOD.

THE services which H.S.H. the Prince of Monaco has rendered to the science of oceanography, during the last ten or twelve years, are familiar to every one interested in that department of research. First in the small schooner *Hirondelle*, with no power but the strong arms of his Breton crew, and later, in the large and perfectly equipped auxiliary steam yacht *Princesse Alice*, there is no branch of the science which has not been enriched by his enlightened enterprise and his unwearied perseverance. It may be interesting to the readers of NATURE to know something of what was achieved in the summer cruise of 1895 in the waters of the North Atlantic, chiefly in the vicinity of the Azores. The dredging and other deep-sea operations conducted on board the yacht herself were very successful, and produced an abundant harvest. The most interesting result of the cruise, however, was due to the lucky chance of a cachalot or sperm whale being pursued by the whale-fishers of Terceira, and killed almost under the bows of the *Princesse Alice*, and to the prompt measures taken by the Prince to utilise this rare opportunity, the importance of which for science he immediately and intuitively perceived. The preliminary reports of the investigation of the material thus collected by the Prince, in collaboration with the Portuguese whalers, go to show

that an almost entirely new and unsuspected animal kingdom has been opened to the zoologist.

A general account of the nature of the results has just been given, under the title "Prise d'un Cachalot," to the Société des Naturalistes, at its meeting in the amphitheatre of the Museum of the Jardin des Plantes, on December 24; and two communications were made, on December 30, to the Academy of Sciences by the Prince, of which one was from Prof. Joubain, of Rennes, dealing especially with the specimens of gigantic cephalopods obtained. It will be convenient to give the proceedings of the yacht, during and after the capture of the cachalot, in the form of an abstract of the Prince's own communications, and to deal with the specific details of the animals collected, in the form of an abstract of Prof. Joubain's paper.

Proceedings of the Yacht.

On July 18 of last year, about nine o'clock in the morning, I observed, while engaged in operations in the deep water to the south of the island of Terceira, two boats leave the coast under sail, and about half an hour later two other boats proceeded in the same direction from another point. It was evident that they were not bound on an ordinary fishing expedition, and I quickly perceived that they were in pursuit of a school of sperm whales or cachalots; and I finished with the greatest speed the work in hand, in order to be able to take full advantage of the rare occasion of being able to assist at the capture of one of these interesting animals, should such be the result of the exertions of the whalers. About eleven o'clock I observed a whale spouting at a distance of about two miles, and I perceived that one of the whalers was approaching it cautiously. I was careful to remain at the same distance, in order not to run the risk of interfering with the whaler, and I closely followed all the manœuvres. The officer or coxswain of the boat stood erect in the stern, steering the boat with an oar. The harponeer stood in the bows, and I distinctly saw him strike the whale. I then approached the group at full speed, while the other whalers dispersed in pursuit of other members of the school. When I had arrived within one or two hundred metres, the cachalot had already towed the whaler attached to it by the harpoon, and the whole length of this line, to a considerable distance, and the harponeer had just succeeded in giving the animal the thrust of the lance, which terminates the struggle if skilfully delivered. The spray thrown out by the animal had become pink, and soon became quite red, while a pool of blood extended itself more and more on the surface of the water around. The *Princesse Alice* was lying at about one hundred metres from the animal when it turned slowly round, lashed out with its tail, and then came straight for the yacht at a speed of ten or twelve knots. As there are many records of whaling ships having been sunk by the cachalot under similar circumstances, it will not be wondered at if I confess to having experienced some anxiety during the approach of the whale, and when powerless to avoid it. Just, however, at the moment when I expected the shock, the whale sounded, passed under the keel without touching it, and reappeared on the other side in the agony of death. The rescue of the yacht from certain damage, if not from destruction, would have been impossible had the life of the whale been spared for a little longer. The cachalot was now floating alongside, with its head at a distance of about fifteen metres from the rudder, when its jaws opened and allowed several objects to escape, which I quickly recognised as cephalopods; but, notwithstanding the speed with which a boat was got away, in order to secure these animals, of the inestimable value of which I had already a presentiment, I perceived that they had begun to sink. On the spur of the moment, I started the engines very slow astern, and the coveted remains circulated slowly in the vortices produced by the propeller until they were secured by the boat.

The vessel now floated in a sea of blood of some acres in extent, and the whalers fixed one of our hawsers to the head of the dead animal; for they had gladly accepted my offer to tow it to El Negrito, where they have their installation for harvesting the oil from the whales that they are lucky enough to catch. The towing operation was not an easy one. The tail, acting as a rudder, caused the animal to swerve so violently from one side to another, that it was necessary to desist from the attempt to tow it head foremost, and to shift the tow-rope to the tail, after which the operation was completed without difficulty. The creek, which was the final destination of the whale, was not a suitable place for the yacht to remain; so, after landing the zoologists, MM. Richard and Lallier, and the artist, M. Borel, she left for the anchorage of Angra, while these gentlemen remained to assist at the breaking-up of the whale, with all the materials necessary for preserving the interesting matter which it promised to furnish.

For four days, under a burning sun, the whalers worked at removing the blubber and transferring it to the neighbouring house, where it was boiled down. At the same time they endeavoured to assist me in every way in securing the portions of the animal which interested me, more especially the brain. But the work was so difficult that it was only at the end of the fourth day that the skull was penetrated, and then the brain was found in a too advanced state of decomposition to be of use for preservation. It was impossible to approach the brain sooner, except by sacrificing the spermaceti, of which the volume was more than a cubic metre, and the commercial value very great. For half a day several men stood up to their middles in the cavity of the head which contains the spermaceti, and ladled it out. It must be remembered that the whale, which was stranded at high water, could only be worked at after the tide had ebbed considerably.

A large number of parasites were collected from the stomach, the digestive organs, the blubber, and the skin of the animal. M. Richard discovered on the lips of the whale certain round impressions, which he identified as the marks of the suckers of the great cephalopods. One can imagine the struggles of the giants which take place deep under the surface of the ocean. Notwithstanding his activity the cephalopod is seized by the cachalot, who, by means of the formidable teeth of the lower jaw, and the corresponding recesses in the upper jaw, holds the body of the animal without hope of escape. The cephalopod, in its defence, envelopes the face and head of the whale with the crown of its tentacles, the suckers of which leave deep impressions on its lips, and other parts where they have fastened. Meantime the cachalot makes efforts to swallow the portion of the cephalopod of which it has really taken possession, with the effect that the part of comparatively small calibre connecting the body with the head gives way; the body is swallowed, and the head dies and either drops off, or is eaten by the whale.

Zoological Details from Professor Joubain's Paper.

The sperm whale or cachalot (*Physeter macrocephalus*, Lacepède), caught on July 18, 1895, measured 13·7 metres in length. While in the act of death, it ejected several large cephalopods which it had only just swallowed, as was evident from their perfect state of preservation. Amongst them were three large specimens, each over one metre in length, of a species, probably new, of the little-known but interesting genus *Histioteuthis*. The bodies of two other immense cephalopods were collected at the same time. When the stomach of the cachalot was opened, it was found filled with a quantity, estimated at over one hundred kilogrammes, of the partially digested débris of these

cephalopods, all of them of enormous size. Amongst this débris may be noticed the crown and tentacles of a cephalopod, the body of which could not be found, belonging probably to the genus *Cucioteuthis*, hitherto known only by a few fragments. The muscular arms, which, though much shrunk and contracted by the preserving liquid, are as thick as those of a man, were covered with great suckers, each armed with a sharp claw, as powerful as those of the larger carnivora. More than one hundred of these suckers remain adhering to the arms.

The bodies of the two great cephalopods constitute one of the most interesting novelties of the scientific cruise of H.S.H. the Prince of Monaco. Their structure and their appearance are so different from all that is known amongst these animals, that it is impossible to place them in any species, genus, or family of this order. I propose for them the name of *Lepidoteuthis Grimaldii*, hoping that the discovery of complete specimens may permit of their affinities being more perfectly defined. One of these animals, half digested, is useless for study; the other, though headless, is much better preserved. It is a female, of which the body or visceral sac, after prolonged immersion in formol and alcohol, still measures 90 centimetres in length, from which it may be concluded that the length of the complete animal would exceed two metres. The surface of the sac is covered with large, solid, rhomboidal scales, arranged spirally like those of a pine cone. The fin (*nageoire*) is very powerful, and forms one half of the length of the body. It is not furnished with scales.

The stomach of the cachalot contained, besides, another cephalopod of large size, provided with a large fin, the skin of which enclosed certain photogenic organs. The head is wanting, so that it is impossible to affirm with certainty that it belongs to a new species, which is made very probable by the form of the body. Finally, the stomach of the cachalot contained a large number of beaks and rays or plumes, the difficultly digestible residue of former repasts.

The cachalot which was killed by the whalers of Terceira, almost under the keel of the *Princesse Alice*, seems as if it had been guided, in the pursuit of its food, by a desire to devour nothing but animals which, up to the present, are completely unknown, and in addition are of the highest importance for the morphology of the cephalopods. These cephalopods are all powerful swimmers, and very muscular. They appear to belong to the fauna of the deep intermediate waters, which is almost completely unknown, at least as regards the larger animals. They never come to the surface, nor do they lie on the bottom of the sea. Their great agility enables them to avoid every attempt to take them by nets; and it would appear that, for the present, the only means of capturing these interesting and gigantic animals is to commission a bigger giant to undertake the task, and to kill him in his turn when he has performed the service.

Accordingly, it is his Highness's intention for next season, either to add to the already very complete fittings of the *Princesse Alice* those of a sperm whaler, or to attach to her a special whaling tender. It need hardly be added, that the further working up of the unique material already collected is being pushed forward with the greatest energy, and the results will be awaited with interest and impatience.

J. Y. BUCHANAN.

NOTES.

MEN of science need no reminder that, however they may be separated by political or racial differences, they are united in the promotion of natural knowledge. Scientific academies and societies in every part of the world delight to admit foreign investigators into fellowship, and to show publicly, by various marks of appreciation, their regard for contributions to known facts of nature, and for assistance in interpreting those already garnered. But though these international amenities are common enough in the world of science, it is but rarely that the Government of one nation does honour to the distinguished men in another. We therefore notice with keen satisfaction that the French Government has just decorated a number of foreign investigators, in connection with the recent centenary of the Institute. Prof. Max Müller has been appointed Commander of the Legion of Honour, and Lord Rayleigh and Prof. Ramsay have been created Officers. The broad feeling that prompted these awards was the same as that which led the French Government to strike special medals to commemorate the late Dr. Hind's discovery of asteroids, and Janssen and Lockyer's method of observing solar prominences in full sunshine; and, more recently, it inspired the Paris Municipal Council to make arrangements for erecting a statue of Newton in Paris. In sharp contrast to the delicate compliments which the French Government and people pay to British science is the insularity which regulates the distribution of those honours that the British Government have at their disposal. So few and so belated, indeed, are the honours conferred upon men of science in our own country, that it is almost vain to think that her Majesty's advisers will one day have the magnanimity to do honour to investigators of other nations. We cherish the hope that the New Year decorations just given to British men of science by France will induce our own Government to return the courtesy.

M. BERTRAND AND M. BERTHELOT, Secrétaires Perpétuels of the Paris Academy of Sciences, have been made Grand Officers of the Legion of Honour. M. Maspero, the distinguished Egyptologist, has been appointed Commander, while Dr. Duclaux, Director of the Pasteur Institute, and MM. Grimaux and Moissan, the eminent chemists, have been created Officers of the same Order. Thus does France honour those who have established their claim "rightly to be great."

PROF. MARK W. HARRINGTON, late Chief of the United States Weather Bureau, and now President of the University of Washington, proposes to establish in the University a department of Terrestrial Physics and Geography, and he would be glad if authors and publishers would send to the University publications relating to these subjects.

A SOCIETY was legally registered in Paris a few days ago, having for its object the propagation of Pasteur's methods in medical treatment. The Administrative Council consists of MM. Duclaux, J. B. Pasteur, Roux, and Radot. The present capital of the Society is £400, in one hundred shares of £4 each, all of which have been taken up.

WHILE all interested in geology will rejoice at the recognition of the services to science and the State rendered by Sir Joseph Prestwich, they will regret to learn he is still in an extremely weak state of health and confined to his bed. Although he has regained a little strength, his convalescence must of necessity be slow.

PROF. SOLLAS, F.R.S., will leave in March for Sydney, to take charge of an expedition that is being despatched to make deep borings in a coral atoll. The scheme, which is supported by a strong scientific committee, has been financed by the Royal Society to the extent of £800; and the Government are placing a gunboat at the disposal of the party, to convey them from Sydney to Funifuti, in the Central Pacific, which has been selected as the scene of operations.

DR. DONALDSON SMITH read an interesting paper at the Geographical Society's meeting, last Monday, on his recent journey from Somaliland to Lake Rudolf. He told the story of the adventures of his expedition during the performance of this feat. The results of the journey are of great scientific importance. Dr. Smith has prepared a useful map, based on careful astronomical observations, of the region to the north and north-east of Lakes Rudolf and Stephanie, which has not hitherto been explored. He has also carried a chain of observations across the Borana country, between the Juba and Lake Rudolf. The collections proved of exceptional interest: in Somaliland, Dr. Smith has discovered an avifauna which is most closely allied to that of the Cape. This is in harmony with some other available evidence, and suggests a former immigration into East Africa from land now submerged beneath the Indian Ocean. He has found in the Borana country a fossil which proves the occurrence of Lower Oolitic rocks there; and thus shows the line of connection between the Jurassic beds of Mombasa with those of Shoa and Somaliland. He has also had exceptional opportunities of study of a dwarf tribe, first reported by Harris in 1844, members of which have only been seen twice previously. Dr. Smith's study of the hydrography of the region around Lake Stephanie has thrown light on the famous controversy as to the course of the Omo, though his observations do not settle it.

THE fact that calcium carbide is now obtainable commercially has been ingeniously applied by M. G. Trouvé for the purposes of domestic lighting. The principle of his lamp is that of the "Kipp" used in chemical laboratories, in various forms, for the production of hydrogen sulphide and other gases. The mode of arranging the contact of the water and carbide had to be carefully worked out, as an ordinary "Kipp," charged with calcium carbide and water, gives such a vigorous evolution of acetylene as to be unmanageable. An estimate of the working cost of the lamp compared with that of coal gas is favourable to the former in Paris, where gas is costly (7*s.* per 1000 feet); but in London, if the carbide could be obtained at the same price (4½*d.* per lb.), the cost would still be double that of ordinary lighting gas.

SOME interesting investigations on the vitality of typhoid bacilli inoculated into oysters have been carried out by Mr. Charles Foote. It appears that during the first fortnight following the introduction of the typhoid bacilli, undoubted multiplication of these microbes took place, but after that time had elapsed a steady decline in numbers was observed. The presence of typhoid bacilli within the oyster was, however, still demonstrable even thirty days after they were first introduced, and they were, moreover, observed in the stomach of the oyster, where they remained unimpaired in a vital condition. In some other experiments the water in which the oysters were immersed was also inoculated with typhoid bacilli, and it was actually found that they lived longer within the body of the oyster than in the water in which the latter was preserved. These investigations materially assist in justifying the hypothesis as to the possible contraction of typhoid through the consumption of oysters.

THE *Publishers' Circular* states that the number of new books issued in England in the course of last year was 5581, and of new editions 935, making a total of 6516 publications. By dividing these works into thirteen classes, an idea is given of the kinds of literature which make up this total. In the educational, classical, and philological class, 660 new-books were published, and 111 new editions. These numbers are a little in advance of those of previous years. The number of new books classified under "Arts, Sciences, and Illustrated Works" is 96, in addition to 16 new editions. But no definite idea with reference to the issue of scientific books can be obtained from these figures, owing to the unsound system of classification adopted. Why illustrated works should be classified with scientific works passes our comprehension. Moreover, there is something wrong about the figures, for in science alone we noticed in these columns last year many more than sixteen new editions of British books. Under the heading "Voyages, Travels, Geographical Research," 263 new books are given and 75 new editions. This was a slight decrease on the publications of 1894. In medicine, surgery, &c., 153 new books were issued and 53 new editions, this being a remarkable increase on the issues of the previous year.

WE note that the table of mean values for pressure, temperature, rainfall, and bright sunshine, which is published in the *Daily Weather Report* issued by the Meteorological Office, has been materially improved this year. In the first place, five more years of observations have been added to those from which the monthly means for each of the elements are calculated. Secondly, new columns have been added, showing the absolute maximum and minimum temperatures recorded during the month and the years in which such extremes occurred. The mean values are now mainly for the twenty-five years 1871–95, and the extreme readings afford valuable information as to whether the maximum and minimum temperatures recorded during each month are exceptionally high or low for the season. A glance at the table for January shows, for instance, that during the last twenty-five years the highest temperature recorded at any station included in it, in that month was 59° at Nairn and Cambridge, and the lowest, – 4° at Wick. Sunshine values at a few more stations would further enhance the value of this otherwise very complete *Report*.

THE "Triton" Society for the study of Aquaria and Terraria in Berlin has recently announced its intention of awarding prizes to the amount of 1500 M. for the best original solutions of certain problems connected with the management of fresh-water aquaria. The competition is open to all, and the problems in question are as follows:—(1) A method for the destruction of the more injurious ectoparasites of fishes, *e.g.* Gyrodactylus, Ichthyophthirius, Chilodon, Myxosporidia; (2) a method of exterminating the fresh-water polyp, Hydra, from aquaria; and (3) a method for exterminating the tube-worm, *Tubifex rivulorum*, from aquaria. In all three cases the methods recommended must be simple, easy to carry out, and effective in their results; but, while fatal to the particular organisms mentioned, they must have no injurious effect upon the fish and plant life of the aquarium. The essays must contain exact accounts of the methods recommended, and full descriptions of the experimental evidence upon which they are based, so that the methods may be readily and accurately repeated. Competitors must write in one of the recognised European languages, and must forward their essays by July 1, 1897, to Prof. F. E. Schulze, Direktor des zool. Instituts, Berlin N., Invalidenstrasse 43. The adjudicators will be Profs. F. E. Schulze and K. Möbius, and Drs. Haack, Hofer, and Schillinger. For the first problem two prizes will be awarded of 700 M. and 400 M. respectively; for each of the remaining problems a prize of 200 M. will be awarded. The Minister of Agriculture will also place two State medals in the hands of the adjudicators for award. Further information in regard to the competition will be found in *Der Zoologische Garten*, Frankfurt, vol. xxxvi. No. 9, 1895, pp. 285, 286.

THE annual general meeting of the Institution of Mechanical Engineers will be held on Thursday evening, January 30, and Friday evening, January 31. The annual report of the Council will be presented to the meeting on Thursday. The retiring President, Prof. Alexander B. W. Kennedy, F.R.S., will induct into the chair the President-elect, Mr. E. Windsor Richards.

The following papers will then be read and discussed, as far as time permits: "Telemeters and Range-finders for Naval and other Purposes," by Profs. Barr and Stroud; "Calculation of Horse-power for Marine Propulsion," by Lieut.-Colonel Thomas English; "Notes on Steam Superheating," by Mr. William H. Patchell.

THE Home Secretary has just issued the following order:—(1) The Wild Birds Protection Act, 1880, shall apply within the administrative county of the Parts of Kesteven, Lincolnshire, to the following wild birds, viz.:—Kestrel, merlin, hobby, common buzzard, honey buzzard, swallow, house martin, sand martin, swift, and wryneck, as if those species were included in the schedule to the Act. (2) The taking or destroying of the eggs of the following wild birds is prohibited within the administrative county of the Parts of Kesteven, Lincolnshire, viz.: Goldfinch, kingfisher, nightjar, nightingale, owls (of all species), ruff or reeve, woodpecker, kestrel, merlin, hobby, common buzzard, honey buzzard, swallow, house martin, sand martin, swift, wryneck, teal, and wild ducks (of all species)."

THE last published number of the U.S. *Weather Review* (June 1895) contains some interesting notes on the early history of weather telegraphy. The Morse telegraph was put into operation between Baltimore and New York on May 27, 1844, and it is said that a few days only had elapsed before the operators began to forewarn each other of the more important weather changes. In the *American Journal of Science and Arts*, vol. ii. 1846, Mr. W. C. Redfield notified that the approach of a gale, when the storm was yet on the Gulf of Mexico, or in the Western States, might be made known by means of the electric telegraph. A similar opinion, by Prof. Loomis, was published in the Second Annual Report of the Smithsonian Institution for the year 1847. A remarkable enterprise was undertaken by a news agency in New York; on January 24, 1848, Messrs. Jones and Co. advertised that they had made arrangements to give daily and hourly reports of meteorological phenomena from all parts of the country which were in telegraphic communication with New York; this advertisement appeared in *Silliman's American Journal of Science* for March 1848. The subsequent steady development of telegraphic weather reports culminated in the publication of daily maps; further particulars respecting the early development of meteorological telegraphy will be found in "Weather Charts and Storm Warnings," by Mr. R. H. Scott.

AN apparatus which illustrates all the laws of falling bodies, and also shows the tension or force acting upon them, is described by K. Hrabowski in *Wiedemann's Annalen*. It consists of a carriage moving on a single rail, somewhat on the Lartigue railway system, pulled by a weight drawn over a pulley, the string being connected to the carriage by a spring moving up and down in a vertical tube. To the upper end of the spring a pencil is attached, which moves along a vertical plate, and leaves a mark as the carriage runs along. When the carriage is at rest, the pencil stops at the point indicating the amount of the moving weight. Immediately on starting, the spring contracts, and the pencil-point traces a curved line which gives the force acting upon the carriage at every point. The line becomes horizontal when the carriage and weight have equal velocities, the tension in the spring being then just sufficient to overcome friction, and the amount of the latter may also be seen at a glance. By inclining the rail, the phenomena of acceleration downwards, or retardation upwards, may be easily studied. The apparatus is cheap, and should form a useful adjunct to science classes.

THE following account of the method used by the Bushmen of Namaqualand to poison their arrows is given in the *Scientific African*:—"Many methods of preparing the poison have been described, and according to some the poison is said to be extracted from the root of the plant, *Buphane toxicaria*, or Gift-bol, but it seems that the extract is only used as a resin. Some resin, either from the Gift-bol or from one of the members of the Euphorbia group of cactus-like plants, is first obtained, and the sticky substance is placed on a stone. The Bushman then goes with a forked stick to look for the 'ring-halse' or black night-adder, not the puff-adder which is called the ring-halse. Having found the snake, by a dexterous thrust of the stick the animal is imprisoned just behind the head by the two prongs of the stick. The prepared stone is then placed in the mouth, and the upper jaw forced right back. By this somewhat rough treatment the poison glands become compressed, and two drops of poison forced out on the fangs and caught on the stone. The poison is then well mixed with the resinous matter, and is ready for use. In the earlier days a more complicated procedure was adopted, through the medium of the witch-doctor. The whole head of the puff-adder was obtained and put in a pot along with the resin, and beetles and noxious herbs added to the incantation of the witch-doctor. The whole was stewed up amid great excitement. When the contents of the vessel were properly mixed, the sticky compound was collected by stirring it with a stick, to which the matter adhered, and on becoming cold, remained on the stick as a black knob, and formed then an article of barter."

A DESCRIPTION of the gold fields of the Southern Appalachians, based on a recent survey by Mr. G. F. Becker, forms part of the latest volume of the "Mineral Resources of the United States." There are a few small placer deposits in this field, which afford but little gold. They are of interest, however, in that they furnish undoubted proofs, in Mr. Becker's opinion, that alluvial gold is not formed by accretion, but by the wearing down of particles already present as such in quartz lodes. He accounts for the high standard of alluvial gold, and especially for that of the outer layers of nuggets, by assuming that the silver and other impurities have been removed in solution by running water; and he clinches his argument by quoting the opinion of Orviedo, one of the lieutenants of Columbus. Mr. Becker further narrates how he has traced the complete transition from hard auriferous quartz to true placer gravels through a series of "saprolites," a name proposed by him to designate "thoroughly decomposed, earthy, but untransported rock." He distinguishes them as "granitic saprolite" and the like, and claims that the use of such a term would be very convenient. The other gold deposits of the Appalachians are mainly true lodes, occupying fissures which run across the planes of stratification and have been formed by purely mechanical action. In this the author differs from Mr. J. A. Phillips, who thought they were "segregation veins." In whatever manner the veins may have been formed, however, there can be no doubt about some deposits of a slightly different kind occurring in Carolina, and bearing much resemblance to the *fahlbands* of Norway. These Carolina *fahlbands* are extensive lens-shaped masses of rock, which are conformable to the general schistose structure of the country, and are charged with disseminated pyrites and gold. Quartz stringers and veins appear close to and even in the rock masses, but, curiously enough, are barren. It is evident that the *fahlbands* have been enriched by impregnation with solutions containing gold, and also that no true segregation has occurred in these cases.

THE production and application of anti-toxic serum in the treatment of rabies has naturally been regarded as a subject the study of which could only be a question of time. The preliminary experiments on this subject made by Messrs. Babès and Lepp in 1889, had not been followed by any great advance in this direction until this year, when a most elaborate and weighty

memoir on the preparation of anti-rabic serum has been contributed to the *Atti della Reale Accademia delle Scienze dell' Istituto di Bologna*, by Messrs. Tizzoni and Centanni. The authors have succeeded in obtaining a powerful anti-rabic serum from sheep by inoculating them seventeen times in the course of twenty days with attenuated nerve-substance obtained from rabid animals, which is introduced in the proportion of 0·75 grm. per kgr. weight of the animal to be treated. Already a few minutes after the serum has been subcutaneously injected, the blood has acquired immunising properties, a result which with Pasteur's anti-rabic method is only obtained after several days, and then not invariably. As a *preventive* measure the authors state that 1½ drops of serum is sufficient to protect an animal weighing 2 kgr. inoculated twenty-four hours later with dog virus. As a *curative* measure the subcutaneous inoculation of 1 cubic centimetre even eight days after the animal has been infected with rabies, and therefore in the middle of the incubation period, is sufficient to stay all further progress of the disease. With this anti-rabic serum, Messrs. Tizzoni and Centanni have been easily able to render rabbits—these animals being especially susceptible to rabies—immune, a result only accomplished under exceptional circumstances by Pasteur's method. Rabbits again, even after the disease has made considerable progress, can be saved by a single subcutaneous injection of anti-rabic serum, whilst the Pasteur method under such conditions has never succeeded in curing them. The authors claim for their method that it is more efficacious, and at the same time less cumbrous than that at present in use. The serum is readily transferable, as it can be desiccated, and kept in bottles, protected from light, for a long time without undergoing any detriment. It thus can be forwarded to all parts of the world, and can be employed by local physicians, therefore preventing delay in treatment, and the necessity of the patient travelling to be treated in special institutes. The further application of anti-rabic serum will be watched with the greatest interest, and the verdict which time and experience alone can furnish will be anxiously awaited.

THE forthcoming number of the *Physical Review* will contain articles on the photometry of differently-coloured lights and the "Flicker" photometer, by Prof. Frank P. Whitman; the chemical potential of the metals, by Mr. Wilder D. Bancroft; and on the freezing-points of dilute aqueous solutions, by Mr. E. H. Loomis.

MESSRS. G. PHILIP AND SON have just published a special coloured map of British Guiana, to illustrate the Venezula-Guiana boundary dispute. The map shows clearly British and Venezuelan territories and claims, the original and modified Schomburgk lines, gold-mining districts, and many other features of the region surrounding the disputed area.

AT the celebration of the second centenary of the death of Christian Huygens, held at Amsterdam in July 1895, Dr. J. Bosscha delivered before the University a valuable address on the life and work of that rare genius. It will interest many of our readers to know that this address, with numerous details appended to it, has been published by Wilhelm Engelmann, Leipzig.

AN illustrated paper "On the Entomology of the Illinois River and Adjacent Waters," by Mr. C. A. Hart, is published in the *Bulletin* of the Illinois State Laboratory of Natural History (vol. iv. pp. 149–273, 1895). The paper gives a part of the results of observation and study of the insect fauna of the Illinois River and adjoining waters in the neighbourhood of the University of Illinois Biological Experiment Station, at Havana, Illinois, during the first year of the station work.

THE "Brief Sketch" of the meteorology of the Bombay Presidency for the year 1894–95 shows that the rainfall of the year 1894 was exceptionally good. During the month of July it was excessively heavy, owing to three severe cyclones, whereby disastrous floods were caused in various districts. The abnormally heavy rainfall on the Ghauts converted the mountain streams into rushing torrents, which swept everything before them, and rendered railway traffic impossible. At Surat a sudden rush raised the level of the river four feet within a quarter of an hour; communication was cut off with all surrounding villages, causing great loss of life from starvation or drowning. It is satisfactory to note that little or no damage was done in the town of Bombay by the immense quantity of rain which fell, owing to the great improvements that have been made in the drainage during the past few years.

LAST year's volume of the *Journal of Conchology* (vol. viii.), which was founded in 1874 by Mr. J. W. Taylor, of Leeds, and ably conducted by him for a period of twenty-one years, contains the record of some important changes which have taken place in the management of the journal during the past twelve months. Four quarterly numbers of the journal were issued during the year. The first informed us that the journal had become, by purchase, the property of the Conchological Society, and would be continued as the official organ of that Society, under the editorship of Mr. W. E. Hoyle. All four numbers contain original papers of varied character and interest, accompanied in some cases by good lithographic or photographic plates of illustrations; and the Proceedings of the Conchological Society, as published in the journal, alone furnish an interesting record of valuable observations in many departments of malacology. The annual report of the Conchological Society for 1894–5 is contained in the July number. From it we learn that all arrangements have been made for the transfer of the headquarters of the Society from Leeds to Manchester, with branches in Leeds and London—a change which, it may be hoped, will contribute still further to the growth and vigour of the Society.

SEVERAL novel scientific instruments and devices described in the new catalogues of scientific apparatus and of lanterns and slides, recently issued by Messrs. Newton and Co., deserve mention here. A very simple method devised to show stereoscopic pictures with the optical lantern is especially noteworthy. A pair of negatives is taken with a stereoscopic camera, and a lantern slide is made from each. One of these slides is mounted in contact with a bluish-green glass, and the other in contact with a red glass. The two slides are simultaneously projected upon a screen, by means of two lanterns, but are not exactly superimposed. The combined picture is then viewed through spectacles, the glasses of which are of the same kind as those covering the slides. Only the red picture is seen through the red glass, and only the bluish-green picture with the bluish-green glass. And as the two pictures are from stereoscopic negatives, a definite stereoscopic effect is produced by making each eye only see one of the pair of pictures, the combination of both of which gives the effect of relief. An advantage which this method possesses is that it can be used with any pair of lanterns. All that is required is stereoscopic slides mounted with suitably coloured glasses, and similarly coloured spectacles through which the pictures must be viewed. Under these conditions, the pictures stand out in strong stereoscopic relief upon the screen. Among the many new forms of instruments described, we notice a new sunshine

recorder, and several improved forms of electric lamps for lanterns. The catalogue of lantern slides should be seen by all who use the lantern in science lectures. It includes Prof. Boys' photographs of "flying bullets," sixty-three slides illustrating volcanic action, from photographs by Prof. Johnston Lavis; photo-micrographs of rock-sections, and many other subjects. The slides are so numerous, and cover so wide a range, that teachers of any and every branch of science will find some in which they will be specially interested.

WE have on our table a number of new editions of books already reviewed in NATURE. One of these is the second edition of the "Lehrbuch der Botanik" (Jena: Gustav Fischer), by Drs. Strasburger, Noll, Schenck, and Schimper. This important work was first published in 1894, and the quick call for a second edition shows that botanists have not been long in finding out its admirable qualities. Dr. Oscar Hertwig's classic "Lehrbuch der Entwicklungsgeschichte" (Gustav Fischer) has now reached its fifth German edition. A number of new figures has been added, and results obtained by embryologists in the two years that have elapsed since the publication of the fourth edition have been incorporated in the text. Another fifth edition recently received is "Dynamo-Electric Machinery" (E. and F. N. Spon), by Prof. S. P. Thompson, F.R.S. The chief changes that have been made relate to alternate-current machinery. These and other additions have been made necessary by the development of electric machinery since 1892, when the fourth edition of Prof. Thompson's elaborate work appeared. A second edition has been published of "Dynamo Attendants and their Dynamos" (*Electricity* Office), by Mr. A. H. Gibbings. The book is intended for those practical men who have charge of electric lighting plant without knowing much about electrical principles; it consists, therefore, mainly of hints and advice as to how to manage dynamos, and what to do under those perplexing circumstances which occur in the best regulated dynamo rooms. After six years, a second edition has been published of "Service Chemistry" (W. B. Whittingham and Co.), by Prof. Vivian B. Lewes. The volume is primarily intended to be an exposition of the applications of chemistry in the naval and military services; nevertheless, a fair proportion of its space is taken up with descriptions of the general principles upon which all technical chemistry depends. Messrs. W. Collins, Sons, and Co. have issued a new edition of "A Manual of Inorganic Chemistry," by Prof. T. E. Thorpe, F.R.S. Since this manual was first published, twenty-three years ago, it has been frequently reprinted, but the new edition contains so much new matter, and is so greatly altered, that it is practically a new text-book, which will be found even more serviceable than the original one. The work is published in two volumes, which deal, respectively, with the non-metals and metals; it has been brought thoroughly up to date, and well records the present state of knowledge of the chemistry of the mineral kingdom.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus sinicus*, ♂ ♂) from India, presented by Mr. F. Greswolde Williams; a Common Marmoset (*Hapale jacchus*) from South-east Brazil, presented by Captain Pickthorn; four Pratincoles (*Glareola pratincola*), four Marbled Ducks (*Anas marmorata*), South European, presented by Lord Lilford; a Snow Bunting (*Plectrophanes nivalis*), European, presented by Mr. J. E. Harting; two Passerine-Parrakeets (*Psittacula passerina*) from Brazil, presented by Mrs. Robert McCabe; a Ring-necked Parrakeet (*Palæornis torquata*) from India, presented by Mr. E. Parrott; a Leadbeaters Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Mr. B. T. Frere; two Leopard Tortoises (*Testudo pardalis*), two Puff Adders (*Vipera arietans*), an Infernal Snake (*Sepedon hæmachates*) from South Africa, presented by Mr. J. E. Matcham; a Manatee (*Manatus australis*) from Demerara, presented by Captain Edward J. Collings; a Southern River Hog (*Potamochœrus africanus*) from South Africa, presented by Mr. W. Anthony Morgan; a Black-handed Spider Monkey (*Ateles geoffroyi*) from Central America, a —— Terrapin (*Hydromedusa tectifera*) from Rio de la Plata, purchased.

OUR ASTRONOMICAL COLUMN.

CELESTIAL PHOTOGRAPHY BY SIMPLE MEANS.—In the hands of Prof. Barnard, the "magic lantern" lens has developed into an instrument of considerable astronomical importance. The lens actually employed by him is a $1\frac{1}{2}$ inch doublet of 4 or 5 inches equivalent focus, and the scale of the pictures is roughly 10° to an inch. Six beautiful photographs of various parts of the Milky Way taken with this small optical aid are reproduced in the *Astrophysical Journal*, vol. ii. No. 5, and they admirably illustrate the value of such an instrument in the delineation of extended nebulosities and in photographing large areas of the sky. They are selected from the more remarkable parts of the Milky Way, but Prof. Barnard has obtained a great number of such photographs, and proposes soon to construct a photographic chart from them. The picture of the new nebulous region in Scorpio shows two very obvious streams or "dark lanes" which are almost void of stars, and various peculiarities are presented by the other photographs.

In the same journal there is a reproduction and an account of a very fine photograph of the nebula near ξ Persei (N.G.C. 1499) taken with an exposure of six hours by means of the 6-inch Willard telescope, at the Lick Observatory, on September 21, 1895. The nebula is very irregular with numerous condensations, and is remarkable for a small dark spot, about 6′ in diameter, in its northern part; "doubtless a hole in the nebula," says Prof. Barnard. Attention is drawn to the suggestive fact that this nebula lies on the edge of a region in which there is a comparative absence of small stars, as noticed also in the case of most of the large diffused nebulæ lately photographed.

THE CONSTANT OF NUTATION.—A new determination of the constant of nutation has been made by Dr. Chandler (*Astronomical Journal*, No. 361). It is based on a discussion of 20,294 observations of stars with the mural circles of Troughton and Jones at Greenwich during the years 1825–1848. In order to eliminate errors due to possible slow changes of the angle between the pole and the zenith, whether strictly or irregularly systematic, it has been considered necessary to employ a large number of stars, distributed as uniformly as possible over the entire sky; and the Greenwich observations offer this facility, while at the same time possessing the necessary degree of accuracy. The adopted mean value of the latitude of Greenwich is 51° 28′ 38″·42, and assuming that this is the same in all years, the nutation is found to be 9″·197, after eliminating the short-period terms of the latitude variation. This assumption, however, is not justified, as the observations indicate a pronounced deviation, which cannot be explained by anomalies of refraction, but must be due to a change in the place of the zenith. Although such a change may possibly be subjective, Dr. Chandler thinks it much more likely to be due to an actual slow change of the latitude. The observations favour an inequality of the mean latitude with a period of about twelve years, and a range of about a quarter of a second. To whatever cause this change may ultimately be ascribed, it is at least necessary to take account of it in evaluating the constant of nutation; and when this and all other corrections have been applied, the definitive value of the nutation, from the observations with the Greenwich mural circles, is 9″·192 ± 0″·012. Combining this result with all previous ones which are entitled to any weight at all, the final value becomes 9″·202. The corresponding reciprocal of the moon's mass, in terms of that of the earth, is 81·80, if 50″·36 be taken for the luni-solar precession.

A YORKSHIRE AEROLITE.

FOLLOWING my recent description of the "Yorkshire Gypsey-Springs," I may say that the great Yorkshire aerolite fell a century ago at the village of Wold Newton, where these springs first rise to light. Wold Newton is ten miles west from Bridlington Quay, no village on the Yorkshire Wolds having so much to interest the students of archæology and natural phenomena. Here, at Wold Cottage, lived Edward Topham, the retired "Tip-top Adjutant," who, in 1787, established *The World*, and whose epilogue, spoken by Lee Lewis in the character of Molière's "Old Woman," created him a star in the dramatic firmament. Two fields south-westerly from Wold Cottage, and protected on the north side by a plantation, you come to a flue-like column of bricks, which used to receive its washing with white lime every year. A yellow slab in the middle bears the following inscription :—

HERE,
on this spot, December 13th, 1795,
fell from the atmosphere
AN EXTRAORDINARY STONE.
In breadth 28 inches,
In length 30 inches,
and
whose weight was 56 pounds.
This column
was erected by
Edward Topham,
1799.

Thus, it is scarcely more than a century since this meteoric stone fell. The day was Sunday, the time about three o'clock in the afternoon, the weather misty, thunder and lightning being at a distance. Suddenly there came a noise like an explosion. George Sawden, a carpenter, was passing within sixty yards of the spot where the aerolite fell; and so much nearer was John Shipley, a farm servant, that he was struck by some soft earth thrown up by the stone when it plunged into the earth. While it was still passing in a north-easterly direction from the sea-coast, a number of persons at Reighton, who, while "turniping" their sheep in the fields, saw it moving down the clouds, made hasty steps for the top of their church-tower to see where it fell, while others spread the tale that it was a cannon-ball shot by a ship-load of French giants who were supposed to have landed to invade the island. Two sons of the Vicar of Wold Newton heard the same body whizz over their heads, and they were among the first on the spot where it fell. It excavated a place 19 inches deep and of something more than 3 feet in diameter, embedding itself so fast in the chalk rock that considerable force was required to dislodge it. A piece split off was, sixty years ago, in the possession of the Rev. Francis Wrangham, F.R.S., Vicar of Hunmanby. It had a black, vitrified surface, and exhibited marks of having been exposed to the action of fire. The inside was white and of a granulated but very compact texture, its composition having no resemblance to any natural stone of the terrestrial sphere. Sent originally to Sowerby's Museum, London, now the aerolite occupies a conspicuous position in the British Museum. It is about the size of a man's head.

HARWOOD BRIERLEY.

PRIZE SUBJECTS OF THE PARIS ACADEMY OF SCIENCES.

AT the recent annual meeting of the Paris Academy of Sciences, the following prizes were announced for the year 1896. In Mathematics the subjects proposed are: the Grand prize for an important improvement in the algebraic theory of groups of substitutions between *n* letters; the Bordin prize (3000 fr.) for an important advance in the theory of geodesic lines; the Francœur prize (1000 fr.) and the Poncelet prize (2000 fr.) will be awarded for discoveries useful in pure and applied mathematics. In Mechanics, the extraordinary prize of 6000 fr. will be given as a reward for an invention tending to increase the efficiency of the French naval forces, the Montyon for the improvement or invention of instruments useful to the progress of agriculture or the mechanical arts, and the Plumey prize (2500 fr.) for improvements in steam engines or any invention contributing to the progress of steam navigation.

In Astronomy, the Lalande prize (540 fr.) wi be awarded to any one (in France or elsewhere) who shall ha\ - made the most interesting observation, or have published the most useful work bearing on astronomy; the conditions for the Valz prize (460 fr.) are similar. The subject announced for the Damoiseau prize (1500 fr.) is to connect together by the theory of disturbances the various appearances of Halley's comet, going back as far as 1456 (Toscanelli), taking account of the attraction of Neptune, and also to calculate exactly the next return in 1910. The Janssen prize (a gold medal) is offered for an important result in Physical Astronomy; a Montyon prize (500 fr.) for studies in French statistics, and the Jecker prize (10,000 fr.) for researches in organic chemistry. In Mineralogy and Geology, the subjects for the Vaillant prize (4000 fr.) are to study the physical and chemical causes which determine the existence of rotatory power in transparent substances, especially from an experimental point of view, and to improve, theoretically or practically, methods relating to geodesy or topography; the Fontannes prize (2000 fr.) is offered for contributions to palæontology.

In Botany, there will be awarded the Demazières prize (1600 fr.) for the best contribution, to our knowledge of the Cryptogamia, the Barbier prize (2000 fr.) for a botanical discovery having special reference to medicine, two Montagne prizes (1000 fr. and 500 fr.) for work bearing on the anatomy, physiology, development, or description of the lower Cryptogams, and the Thore prize (200 fr.) for the best memoir on European cellular Cryptogams. In Anatomy and Zoology, the Savigny prize (975 fr.) is given to aid young travellers, who, not receiving Government assistance, specially occupy themselves with the Syrian and Egyptian invertebrates. One or more Montyon prizes will be awarded for discoveries in Medicine and Surgery, the Bréant prize (100,000 fr.) for a specific cure for Asiatic cholera. Other prizes offered in Medicine are the Godard prize (1000 fr.) for the best memoir on the anatomy, physiology, and pathology of the genito-urinary organs, the Serres prize (7500 fr.) for the best work on general embryology applied to physiology and medicine, the Bellion prize (1400 fr.) for work of especial value to the public health, the Mège prize (10,000 fr.) for an essay on the causes which have helped or retarded the progress of medicine, and the Lallemand prize (1800 fr.) for researches on the nervous system. In Physiology, besides a Montyon prize (750 fr.), there is offered the Philipeaux prize (890 fr.) for experimental physiology, and the Pourat prize (1800 fr.).

In Physical Geography, the subject announced for the Gay prize (2500 fr.) is a study of the French lakes from a chemical, physical, and geological point of view. Besides the Arago medal, which is only occasionally awarded for discoveries of special value, the following general prizes are offered for 1896. The Montyon prize (unhealthy trades) for a means of rendering less dangerous an unhealthy trade, the Trémont prize (1100 fr.) the Gegner prize (4000 fr.), the Delalande-Guérineau prize (1000 fr.), the Jean Reynard prize (10,000 fr.), the Jérome Ponti prize (3500 fr.), the Tchihatchef prize (3000 fr.) for the exploration of imperfectly known regions of Asia, the Houllevigue prize (5000 fr.), the Cahours prize (3000 fr.) for the encouragement of young men already known as having done interesting work, especially in chemistry, the Saintour prize (3000 fr.), the Laplace prize of books, and the Rivot prize (2500 fr.).

In the case of the prizes bearing the names of La Caze, Delesse, Desmazières, Lalande, and Leconte (in 1898), it is specially stated that they are awarded entirely without preference of nationality, and of the remainder only two or three are restricted to French subjects. All memoirs for this year must be sent in to the Academy before June 1.

AMATEUR CLOUD PHOTOGRAPHY.[1]

THE blue colour of the sky has as much action on an ordinary sensitive plate as the white colour of light clouds (cirrus and cirro-cumulus); it is therefore necessary to diminish the action of the blue background of the sky. For this purpose a yellow screen is placed so as to intercept the rays; the light coming from the sky contains very few yellow and green rays, and is thus extinguished to a great extent; but, on the other hand, the great proportion of yellow and green rays which exists in the white light of the clouds passes the screen and makes an impression on the plate, if it has been made more sensitive to the action of yellow and green rays than the ordinary plates.

There are, therefore, three points to be considered: (1) the coloured screen; (2) the sensitive plate; (3) the method of development of the images.

(1) *The Coloured Screens.*—Coloured screens formed of films of

[1] By M. Angot. (Translated from *Cosmos*, November 23, 1895.)

gelatine or collodion must be rejected, because their tint changes very quickly in the light, and they easily lose their transparency. Either yellow glass must be used, or cells containing a suitable liquid.

Yellow glasses make the most convenient screens of all; but the difficulty is to find suitable glasses which are always the same, and of sufficiently graduated shade. Some are excellent, others not worth anything. Before recommending the use of coloured glasses exclusively, some experiments ought to be made with the help of a glass maker, in order to ascertain what ought to be the exact composition of the glass so that it may be reproduced with the exact tone at any time. It is unnecessary to add that the glass must be homogeneous and polished with quite parallel surfaces; only glass ought to be used which is coloured in mass, and not white covered with a superficial layer of enamel.

The surest method, in the case of not being able to get glass of which the composition is known, would be to use liquid screens, as I do. They are made with two parallel square glasses cemented together on three sides by square glass rods also with parallel sides, and with a thickness of six or seven millimetres, and length of side seven to eight centimetres, one side remaining open. If one does not wish to go to the trouble of making them, these cells can be obtained from instrument-makers. Needless to say that before cementing, the glasses must be carefully cleaned with a solution of carbonate of soda, then with water, and lastly by being well rubbed with a piece of cotton-wool dipped in alcohol; with these precautions, no air is to be feared along the sides of the cells. Before introducing the liquid, care must be taken to dip the open end of the cell in a bath of resin (a mixture of yellow wax and resin of equal parts). For ultimately closing the cell, it suffices to fasten on the edges, thus covered with resin, a little plate of glass cut to a suitable size, and which must be heated on a plate of copper to prevent its breaking. If found desirable the aperture may be still more securely closed with sealing-wax. Thus cells are obtained hermetically sealed, which can be used at every inclination without the liquid spilling and without air getting along the joints.

The easiest way of fixing these cells in position is to pierce a circular hole in the centre of a flat piece of cork, the size of the sunshade of the lens of the camera. The plate is fitted into the sunshade and held by india-rubber. The screen is thus in front of the lens, and it can be easily replaced by others more or less dark.

For the liquid, I have had to reject all solutions of organic colours, such as aurentia, primuline, chrysoidine, for they alter in the light. The simplest one is to use the bichromate of potash. A saturated solution is prepared at ordinary temperature, to which is added, after straining, a few drops of hydrochloric acid. This saturated solution, introduced into one of the previously described cells, constitutes screen (1), which should be used when the clouds are very light, and the sky of a pale blue. A solution of half the strength forms screen (2), which may be used for well-lighted detached cirrus on a really blue sky; lastly, screen (3), consisting of one part of the saturated solution to three of water, should be reserved for very luminous clouds as cumulus and cumulo-nimbus.

It is certainly more convenient and more simple to use coloured glasses as screens; but while there is a doubt as to finding suitable glass, we can always be certain when using bichromate cells of straightway obtaining excellent screens, always precisely the same. The ones I possess have been in use two years, and no precautions have been taken to preserve them.

(2) *Sensitive Plates.*—Special plates must be used for yellow light. The way of preparing these plates by means of ordinary plates is already well known; I did this at first. But I am certain that the necessity of preparing the plates is the principal obstacle which stops people taking photographs of clouds, who are really desirous of doing so. However, prepared plates are to be had in the trade, and they serve the purpose admirably.

Among the types of plates called orthocromatic or isochromatic, two have given me excellent results: Lumière's orthochromatic plates, sensitive to yellow and green light, and Edward's orthochromatic plates.

There is, therefore, no necessity to prepare plates, as they are to be had ready-made, and, at least in most cases, quite as good as those one could prepare personally. It has been said that the sensitiveness of these plates alters very soon, so much so that they are useless at the end of a few months. With regard to this, I can but quote the following fact. In February 1893, I received from the firm of Lumière, three boxes of orthochromatic plates, of which the date of manufacture is unknown to me. These three boxes were simply placed in a cupboard of my bureau without any other precautions. The first box of twelve plates was used in the course of 1893; the second, only opened at the beginning of 1894, and used between the months of March and November; lastly, the third box was opened only in November 1894, and the two first plates gave negatives which did not differ at all from those obtained from similar plates twenty months before.

Other similar boxes opened, then forgotten, for some months in a cupboard, have always given me excellent results.

I intend to continue these studies; but it seems to me now established, that if the sensitiveness of these plates diminishes with time, this diminution is small enough to permit of the plates being used after more than eighteen months. Under these conditions nothing can be said against their use.

Focussing is done without any difficulty on a distant object, for instance on a house in bright light. If the horizon is not far enough distant, an object can be taken comparatively near (at least twenty-five or thirty metres), then in order that the position shall correspond with infinity, move the ground-glass towards the lens a distance $\frac{f}{k-1}$, f being the focal distance of the lens, and k the number of times that the distance of the object which has been focussed contains the focal length of the lens. For instance, if an object twenty metres distant has been focussed with a lens, of which the focal length is twenty-five centimetres, then we get $k = \frac{2000}{25} = 80$. In order that the clouds may be in focus, the ground-glass must be brought a distance of $\frac{25}{79} = 0{\cdot}32$ c.m., about 3 millimetres, nearer the lens. Of course the focus must be got with the coloured screen, and the position thus found must be marked on the base of the camera, in order that the position of the frame may be known.

(3) *Development.*—No mode of development must be rejected *à priori*; even developers called *automatic*, which can be bought ready prepared. and which have been very much run down, for they are by far the most convenient, and often give excellent results.

If the negative that we wish to develop contains only clouds of more or less the same intensity, the automatic developers may be used without any risk. I have used baths of hydroquinone, Lumière's developer (of paramidophenol), &c., with success. It is advantageous to use baths which have already been used, and consequently containing a good proportion of bromide; a greater contrast is then obtained between the clouds and sky, and the development can be carried further without fear of fogging.

If, on the contrary, the negative consists of clouds of very unequal luminous intensity, as, for instance, delicate cirrus and strongly lighted cumulus, the negative would not turn out well with automatic developers containing much bromide; the image of the cumulus would appear, and be over-developed before that of the cirrus had begun to show itself. In this case either a new bath must be used, very diluted, without bromide, and the development is then very slow, or else (which is preferable) use pyrogallic acid, in employing the method recommended by M. Londe. In this case the development must be commenced with a very small quantity of pyrogallic acid, a little bromide, and relatively enough carbonate of soda, in such a way as to make all the parts of the image appear at first, without much intensity; then the necessary intensity will be obtained little by little, by the successive additions of pyrogallic acid. It is in this case only, where the intensity of the clouds is very different, that I think it advantageous to recommend progressive development instead of pyrogallic acid. In most ordinary cases, however, the automatic developers, which are more rapid, and more convenient to use, act very well.

In fact it is always as well to continue the development till the image is sufficiently dense, without intensifying, which is almost always possible. Negatives ought only very exceptionally to be intensified; to my mind, the intensification is always bad, it spoils the detail; a renewed or feeble negative is never worth as much as one that was made sufficiently dense in the first instance.

If I have gone into all these details, it is only to show that photography of clouds is a very easy operation, and within the reach of all amateurs. And let me just add, that with the darkest screen (saturated bichromate) and Prazmowski's lens, with a focus of 160 millimetres, and diaphragm of $\frac{1}{30}$, I obtain negatives with a maximum exposure of six seconds for cirrus, with an ordinary amount of light with a Zeiss' object-glass, a diaphragm of $\frac{1}{15}$ and very bright cirrus, having an exposure of $\frac{1}{30}$ of a second, has sometimes been more than sufficient, even too much.

It would be very interesting if amateurs in photography, so numerous at the present time, would try to photograph clouds which strike them as having interesting shapes, noting with care the hour when they were taken, and also the direction in which the clouds appeared.

SCIENCE IN THE MAGAZINES.

ONE of the most interesting contributions to this month's magazines is an illustrated account in the *Century* by Mr. Borchgrevink, of his voyage in the *Antarctic*, prefaced by a note by Mr. A. W. Greely. The article will give an impulse to the movement in favour of an expedition to explore the Antarctic continent. Referring to Mr. Borchgrevink's account, Mr. Greely says: "From a scientific standpoint the interest depends entirely upon the discovery by Borchgrevink, on Possession Island and Cape Adare, Victoria Land, of a cryptogamous growth, probably an unidentified lichen. The importance of this discovery rests in the fact that hitherto no land vegetation of any kind or description had been found within the confines of the Antarctic circle. The strained deduction has been drawn that the climatic conditions of the Antarctic zone must have changed since the voyage of Ross, who discovered no vegetation. It should be borne in mind, however, that the great botanist, Sir Joseph Hooker, who served with Ross, was unfortunately prevented from landing with his commander; otherwise it may not be doubted that low forms of vegetable life which escaped the attention of Ross would have been noted by Hooker. In a practical way it emphasises the possibility of much more extended exploration in the Antarctic Ocean, through the agency of the steam-power of to-day, than was practicable for the greatest of Antarctic navigators—Cook, Balleny, Weddell, Wilkes, and Ross—under sail alone in the past." Ethnologists will be interested in the studies of Indian life given by Alice C. Fletcher in the *Century*, under the title "Tribal Life among the Omahas."

An illustrated description of the magnificent new building of the Boston Public Library, contributed by Mr. T. R. Sullivan to *Scribner*, shows how very thoroughly the American people are working for the advancement of learning. The building will hold a million and a quarter volumes, and everything has been done to make it beautiful, while all that modern contrivance can offer has been utilised to secure comfort. "The reference reading-room of the library," we read, "and its seven thousand volumes are free to all who care to take them down, without the intervention of an attendant. At the southern end, always open for consultation, is the card-catalogue of all the books contained in the building; any one of these will be furnished and brought from the main library to the designated table at a few moments' notice. There is room for hundreds of readers to sit here from early morning to a late hour of the night in undisturbed pursuit of knowledge. Those who have tried to work in the overcrowded libraries of Europe, hampered by annoying restrictions and wearisome delays, will fully comprehend the blessing which such freedom brings." In the same magazine there is an article on "Water-ways, from the Ocean to the Lakes," by Mr. T. C. Clarke, dealing chiefly with the great canal from Lake Erie to the Hudson River. In the editorial notes, reference is made to recent gains in the speed of travel. It appears that the distance between Buffalo and Chicago—512 miles—has been covered at a rate of over sixty-five miles per hour, stops excluded. The distance between New York and Washington is now done in about five hours, but a railway exists (on paper) the trains of which are to shoot over this distance of 240 miles in two hours! The track is to be elevated above the ground on a single line of upright piers, and the trains are to be driven by electricity, each car carrying its own motor machinery. The most distinctive mechanical feature of the enterprise is the so-called "bicycle" arrangement, by which a single line of wheels run on single rail. The train is to be kept upright by an auxiliary rail on each side, which will not, however, come into play except in rounding curves.

In the *Popular Science Monthly* Prof. G. F. Wright discusses the "New Evidence of Glacial Man in Ohio," afforded by a small chipped chest implement found by a trustworthy observer close to Brilliant Station on the Ohio River. He concludes that the discovery "must go far to close the question of man's antiquity on the Western continent, and to dispel the doubts upon the subject which, for one reason or another, have heretofore existed." Prof. James Sully continues, in the same magazine, his "Studies of Childhood," and among the other articles are "The Anatomy of Speed Skating," by Mr. R. Tait McKenzie; a criticism by Mr. Le Sueur of Prof. Forbes' article on the work of the Cataract Construction Company, published in *Blackwood's Magazine* for September 1895; "Health Experiments in the French Army," by Mr. Stoddard Dewey; and "Prehistoric Engineering at Lake Copais," by Mr. J. D. Champlin.

Mr. W. H. Mallock continues in the *Contemporary* his essay on "Physics and Sociology." He holds that the struggle which causes social progress is a struggle of the few against the few, and is fundamentally different from the Darwinian struggle for existence. In his words: "Within the limits of the minority, composed of the exceptionally gifted, whether their gifts are those of scientific knowledge, or knowledge of men's characters and wants, or of a power to direct men, there does undoubtedly take place a struggle strictly analogous to that with which Darwinian science has familiarised us, the result being, as Mr. Spencer's celebrated formula expresses it, the survival of the fittest. Only it is not a struggle for existence, if the word existence is taken to mean life; it is a struggle for existence in a position of rule or domination. It is, moreover, not a struggle with the majority of the community, but with the minority only. The fittest, the survivors, the winners, instead of depriving the majority of the means of subsistence, on the contrary, increase those means, and their unsuccessful rivals are defeated, not by being deprived of the means of living, but only of the profits and privileges that come from directing others. That there is a subsidiary struggle amongst the majority, a struggle to obtain work, not to direct work, is true, as has been said already; but, as has been said also, this is not the struggle which primarily either causes the advance of civilisation or maintains such advances as have been made. It contributes to these results, and how far and in what way it does so will require to be discussed hereafter; but it is not the principal, it is not the primary cause of them. The primary cause is the struggle which causes the survival, not of the largest number of men of average capacity, but of the largest number of men of exceptional capacity—the largest number of great men." Thus, according to the argument, the *domination* of the fittest is the true counterpart in the social world of the *survival* of the fittest in the physiological world. The *Contemporary* also contains a short paper by Mr. Herbert Spencer, on the development of the architect, the paper being the ninth of a series on "Professional Institutions." The view is taken that "the earliest architecture bequeathed by ancient nations was an outcome of ancestor-worship."

In *Science Progress*, Dr. H. E. Armstrong describes "The Plan of Research in Education," and makes a powerful plea for scientific teaching and scientific research, both on account of education and industrial progress. Prof. F. O. Bower discusses recent work on mosses and ferns, with special reference to Prof. Campbell's volume on the subject; Mr. J. W. Rodger continues his statement of "The New Theory of Solutions"; Mr. Philip Lake describes "The Geology of Egypt"; and Mr. G. T. Holloway traces "The Evolution of the Thermometer."

A brief mention will suffice for the remaining articles in the magazines received by us. *Good Words* has a short illustrated paper on sponges, by the Rev. T. Bird, and one on "A School of Mackerel," by Mr. Edward Step. The *Strand Magazine* has several splendid reproductions from photographs of frost patterns on window-panes, obtained by Mr. James Leadbeater. The *Phonographic Quarterly Review* always contains two or three scientific articles. The current number has in it "In a Canadian Forest," by General Sir Charles Wilson, K.C.B., F.R.S. "St. Bartholomew and his Hospital," by Dr. W. R. Gowers, F.R.S., and several other articles of interest to scientific phonographers. The *Fortnightly* has an article on "The Climate of South Africa," by Dr. R. Roose; and among the information articles in

Chambers's we notice one descriptive of the Loofah, or Luffa, by Prof. Carmody.

We have received, in addition to the magazines and reviews named in the foregoing, the *Humanitarian*, *Sunday Magazine*, *National*, *English Illustrated*, and *Longman's*, but the articles in them do not call for particular comment in these columns.

RECENT PROGRESS IN OPTICS.[1]

THE reviewer who aspires to give an account of recent progress in any department of science, is met at the outset by two causes for embarrassment. What beginning shall be selected for developments called recent? What developments shall be selected for discussion from the mass of investigations to which his attention has been called? So rapidly is the army of workers increasing, and so numerous are the journals in which their work is recorded, that the effort to keep up with even half of them is hopeless; or, to borrow a simile employed by the late Prof. Huxley, "we are in the case of Tarpeia, who opened the gates of the Roman citadel to the Sabines, and was crushed under the weight of the reward bestowed upon her."

I have selected a single branch of physics, but one which can scarcely be treated rigorously as single. From the physical standpoint optics includes those phenomena which are presented by ether vibrations within such narrow limits of wave-length as can affect the sense of sight. But these waves can scarcely be studied except in connection with those of shorter and of longer period. Whatever may be the instruments employed, the last one of the series through which information is carried to the brain is the eye. The physicist may fall into error by faulty use of his mathematics: but faulty use of the senses is a danger at least equally frequent. Physiological optics has of late become transferred in large measure to the domain of the psychologist; but he in turn has adopted many of the instruments, as well as the methods, of the physicist. The two cannot afford to part company. If I feel particularly friendly to the psychologist, more so than can be accounted for by devotion to pure physics, it may be fair to plead the influence of old association. If I am known at all in the scientific world, the introduction was accomplished through the medium of physiological optics. But, with the limitations imposed, it is not possible even to do justice to all who have done good work in optics. If prominence is assigned to the work of Americans, it is not necessary to emphasise that this Association is made up of Americans; but, with full recognition of the greater spread of devotion to pure science in Europe, of the extreme utilitarian spirit that causes the value of nearly every piece of work in America to be measured in dollars, we are still able to present work that has challenged the admiration of Europe, that has brought European medals to American hands, that has been done with absolute disregard of monetary standards; work has been recognised, even more in Europe than in America, as producing definite and important additions to the sum of human knowledge.

In drawing attention to some of this work it will be a pleasant duty to recognise also some that has been done beyond the Atlantic—to remember that science is cosmopolitan. The starting-point is necessarily arbitrary, for an investigation may last many years and yet be incomplete. To note recent progress, it may be important to recall what is no longer recent.

Light Waves as Standards of Length.

You are therefore invited to recall the subject of an address to which we listened in this section at the Cleveland meeting in 1888, when Michelson presented his "Plea for Light Waves." In this he described the interferential comparer, an instrument developed from the refractometer of Jamin and Mascart, and discussed various problems which seemed capable of solution by its use. In conjunction with Morley he had already used it in an inquiry as to the relative motion of the earth and the luminiferous ether (*American Journal of Science*, May 1886, p. 377), and these two physicists together worked out an elaborate series of preliminary experiments (*ibid.*, December 1877, p. 427) with a view to the standardising of a metric unit of length in terms of the wave-length of sodium light. By use of a Rowland diffraction grating, Bell had determined the sodium wave-length with an error estimated to be not in excess of one part in two hundred thousand (*American Journal of Science*, March 1887, p. 167). Could this degree of accuracy be surpassed? If so, it must be not so much by increased care in measurement as by increase of delicacy in the means employed. The principle applied in the use of the interferential comparer is simple enough; the mode of application cannot be clearly indicated without a diagram, but probably all physicists have seen this diagram, for it was first brought out eight years ago (*ibid.*, December 1887, p. 427). By interference of beams of light, reflected and transmitted by a plate of plane parallel optical glass, and then reflected back by two mirrors appropriately placed, fringes are caught in an observing telescope. One of the mirrors is movable in front of a micrometer screw, whose motion causes these fringes to move across the telescopic field. If the light be absolutely homogeneous, the determination consists in measurement of the distance through which the movable mirror is pushed parallel to itself and the counting of the number of fringes which pass a given point in the field of view. According to the theory of interference the difference of path between the distances from one face of the plate to the two mirrors should be small; beyond a certain limit interference phenomena vanish, and this limit is smaller in proportion as the light is more complex. In the case of approximately homogeneous light there are periodic variations of distinctness in the fringes. For example, assume sodium light, which in the spectroscope is manifested as a pair of yellow lines near together. In the refractometer there are two sets of interference fringes, one due to each of the two slightly different wave-lengths. When the difference of path is very small, or nearly the same for both of these radiation systems, the fringes coincide. The wave-length for one is about one-thousandth less than that for the other. If the difference of path is about five hundred waves, the maximum of brightness for one system falls on a minimum of brightness for the other, and the fringes become faint. They become again bright when the difference of path reaches a thousand wave-lengths. The case is entirely similar to the familiar production of beats by a pair of slightly mistuned forks.

The method of interference thus furnishes through optical beats a means of detecting radiation differences too minute for resolution by ordinary spectroscopic methods. Spectrum lines are found to be double or multiple when all other means of resolving them fail; and the difficulty of attaining truly homogeneous light is far greater than was a few years ago supposed. By the new method it becomes possible to map out the relative intensities of the components of a multiple line, their distance apart, and even the variations of intensity within what has for convenience been called a single component. Each of the two sodium lines is itself a double whose components are separated by an interval about one-hundredth of that between the long-known main components; and an interval yet less than one-fifth of this has been detected between some of the components of the green line of mercury. Indeed Michelson deems it quite possible to detect a variation of wave-length corresponding to as little as one ten-thousandth of the interval between the two main sodium lines (*Astronomy and Astrophysics*, p. 100, February 1894.)

This new-found complexity of radiation, previously thought to be approximately if not quite simple, proved to be a temporary barrier to the accomplishment of the plan of using a light-wave as a standard of length. It necessitated careful study of all those chemical elements which give bright lines that had been supposed to be simple. The red line of cadmium has been found the simplest of all those yet examined. The vapour in a rarefied state is held in a vacuum tube through which the electric spark is passed, and under this condition the difference of path for the interfering beams in the refractometer may be a number of centimetres. A short intermediate standard, furnished with a mirror at each end, is now introduced into the comparer, and moved by means of the micrometer screw. Its length is thus measured in terms of the cadmium wave-length. A series of intermediate standards, of which the second is double the first, the third double the second, &c., are thus compared, and finally in this way the value of the metre is reached.

The feasibility of this ingenious method having been made apparent, Michelson was honoured with an invitation from the International Bureau of Weights and Measures to carry out the measurement at the observatory near Paris, with the collaboration of the director M. Benoît. After many months of labour, results of extraordinary accuracy were attained. For the red line of

[1] Address delivered by Prof. W. LeConte Stevens before the Section of Physics of the American Association for the Advancement of Science, at the Springfield meeting, August 1895.

cadmium at an air temperature of 15° C. and pressure of 760 mm., two wholly independent determinations were made. From the first a metre was found equal to 1553162·7 wave-lengths; from the second, 1553164·3 wave-lengths, giving a mean of 1553163·5 the deviation of each result from the mean being very nearly one part in two millions ("Travaux et Mémoires du Bureau Internationale des Poids et Mésures," Tome xi. p. 84, 1894). A determination by Benoît from the first series gave 1553163·6, which differs but one-tenth of a wave-length from the mean of Michelson's measurements.

The direct comparison of the lengths of two metre bars, though not easy, is a simple operation in comparison with the indirect method just described, but does not surpass it in accuracy. Every one knows that the metre is not an exact submultiple of the earth's circumference, and that the determination of its exact value from the seconds pendulum is full of difficulty. It may perhaps be said that the optical method is no more absolute than the pendulum method, for no human measurements can be free from error; that there is no possibility of the destruction of the original metre and all certified copies of it; and that there is no proof or probability that molecular changes are gradually producing modifications in standards of length. Even if we should grant that for all practical purposes the labour of determining the metre in terms of an unchanging optical standard has been unnecessary, the achievement is a signal scientific triumph that ranks with the brilliant work of Arago, Fresnel and Regnault. In preparation for it much new truth has been elicited, and light waves have been shown to carry possibilities of application that Fresnel never suspected.

The physicist is nearly powerless without the aid of those who possess the highest order of mechanical skill. The interferential comparer could never have been ultilised for such work as Michelson has done with it, had not Brashear made its optical parts with such an approach to perfection that no error so great as one-twentieth of a wave-length could be found upon the reflecting surfaces ("Travaux et Mémoires du Bureau Internationale des Poids et Mésures," Tome xi. p. 5, 1895). In the conception, mechanical design and execution, the entire work has been distinctly American.

The interferential refractometer has been used with much skill by Hallwachs (*Wiedemann's Annalen*, Band 47, p. 380, and Band 53, p. 1) for comparing the variation of refractive index of dilute solutions with variation of concentration. The fact of solution brings about a change of molecular constitution, affecting both the electric conductivity and the refractive index; and the changes in optical density are measurable in terms of the number of interference fringes which cross the field of view for a given variation of dilution.

LUMINESCENCE.

While all work on the visible spectrum is confessedly optical, we can no longer make an arbitrary division point, and declare that one part of the spectrum belongs to the domain of optics and the other not. Since the days of Brewster and the elder Becquerel fluorescent solutions have enabled us to bring within the domain of optics many wave-lengths that were previously invisible. Stokes's explanation of this, as a degradation of energy quite analogous to the radiation of heat from a surface on which sunlight is shining, has been generally accepted. But whether the phenomena of fluorescence and phosphorescence are in general physical or chemical, has for the most part remained unknown or at least very uncertain. E. Wiedemann, who suggested the term luminescence to include all such phenomena, published in 1895 (*Annalen der Physik und Chemie*, p. 604, April 1895), in conjunction with Schmidt, a part of the outcome of an extended investigation undertaken with a view to clearing up these uncertainties. He has shown that it is often possible to distinguish between cases in which the emission of light springs from physical processes and those in which it is due to chemical action, or at least invariably accompanied by this. We have here, as in photography, a transformation of radiant into chemical energy, to which is superadded the retransformation of chemical into radiant energy of longer period, and this either at the same time or long after the action of the exciting rays. Indeed, between this process and that of photography in colours, the analogy is quite striking. What has generally been called phosphorescence is well known to be the effect of oxidation in the case of phosphorus itself and in that of decaying wood or other organic matter, which under certain conditions shines in the dark.

Wiedemann has shown that the shining of Balmain's luminous paint, and generally of the sulphides of the alkaline earths, is accompanied with chemical action. A long period of luminosity after the removal of the source renders highly probable the existence of what he now calls chemi-luminescence. A large number of substances, both inorganic and organic, have been examined both by direct action of light and by the action of kathode rays in a controllable vacuum tube through which sparks from a powerful electric influence machine were passed. Careful examination with appropriate reagents before and after exposure was sufficient to determine whether any chemical change had been produced. Thus the neutral chlorides of sodium and potassium, after being rendered luminous by action of kathode rays, are thereby reduced to the condition of subchloride, so as to give a distinctly alkaline reaction.

Many substances, moreover, which manifest no luminescence at ordinary temperatures after exposure, or which do so for only a short time, become distinctly luminescent when warmed. This striking phenomenon is sufficient to warrant the use of a special name, thermo-luminescence. Among such substances may be named the well-known sulphides of the alkaline earths, the haloid salts of the alkali metals, a series of salts of the zinc and alkaline earth groups, various compounds with aluminium, and various kinds of glass. Some of these after exposure give intense colours when heated, even after the lapse of days or weeks. That the vibratory motion corresponding to the absorption of luminous energy should maintain itself for so long a time as a mere physical process is highly improbable if not unparalleled. That it should become locked in, to be subsequently evoked by warming, certainly indicates the storing of chemical energy, just as the storage battery constitutes a chemical accumulator of electrical energy. Other indications that luminescence is as much a chemical as a physical phenomenon are found in the fact that the sudden solution of certain substances is accompanied by the manifestation of light, if they have been previously subjected to luminous radiation, but not otherwise: that alteration of colour is brought about by such exposure; and that friction or crushing may cause momentary shining in such bodies as sugar. There is no conclusive direct evidence thus far that such luminescence as vanishes instantly upon the withdrawal of light is accompanied by chemical action. But Becquerel demonstrated long ago with his phosphoroscope that there is a measurable duration of luminous effect when to the unaided eye the disappearance seems instantaneous (Becquerel, *Comptes rendus* 96–121). Wiedemann now shows that when this duration is considerable there is generally chemical change. Since duration is only a relative term it seems highly probable that even cases of instantaneous luminescence, commonly called fluorescence, are accompanied with chemical action on a very minute scale, and that all luminescence is therefore jointly physical and chemical in character. We have thus colour evoked by the direct action of light, which disturbs the atomic equilibrium that existed before exposure, and the manifestation of such colour continues only until the cessation of the chemical action thus brought into play.

The influence of very low temperature upon luminescence and photographic action has been studied by Dewar (*Chemical News*, lxx. p. 252, 1894). The effect of light upon a photographic plate at the temperature of liquid air − 180° C. is reduced to only a fifth of what it is at ordinary temperature; and at − 200° the reduction is still greater, while all other kinds of chemical action cease. In like manner, at − 80° calcium sulphide ceases to be luminescent; but, if illuminated at this low temperature and then warmed, it gives out light. At the temperature of liquid air many substances manifest luminescence which ordinarily seem almost incapable of it; such are gelatine, ivory, and even pure water. A crystal of ammonium platinocyanide, on the other hand, when immersed in liquid air and illuminated by the electric light, shines faintly when this is withdrawn. If now the liquid air be poured off so that the crystal rises rapidly in temperature, it glows brightly.

LUMINESCENCE AND PHOTOGRAPHY.

Photography, like luminescence, is a manifestation of the transformation of energy, most frequently of initial short wave-length. The production of colour by photography is nothing new. It was noticed by Seebeck nearly a century ago that silver chloride becomes tinted by exposure to ordinary light, with accompanying chemical change; that if then subjected a long time to red light it assumes a dull red hue, or a dull

bluish hue if held in blue light. It is likewise possible by proper selection of luminescent salts to produce a selected series of tints during and after exposure to those rays which are most effective in photography. But such colours cannot be made fixed and permanent. The problem of securing on the photographic plate a faithful and lasting reproduction of the various tints of a spectrum thrown upon it has baffled most of those who grappled with this subject. That it has been fully and quite satisfactorily solved cannot yet be affirmed, but the last few years have brought a far nearer approach to success than an equal number of decades previously. Viewed from the scientific standpoint the goal has certainly been touched, even if commercial demands are still made in vain.

STATIONARY LIGHT WAVES.

Two quite different methods are to be considered in tracing the recent development of this interesting application of optical principles. The first is originally due to Becquerel (*Am. de Chimie et de Physique* (3), p. 451, 1848), but lately, in the hands of Lippmann, it has been improved and brought much nearer to success than by its originator. It depends upon the production of stationary waves of light. Every one is familiar with the formation of stationary waves upon an elastic stretched cord, and with the acoustic exhibition of stationary air waves in a closed tube by Kundt's method of light powders. That similar loops and nodes must be produced under proper conditions by interference of waves of light would appear obviously possible; and so long ago as 1868 Dr. Zenker "Lehrbuch der Photochromie," Berlin, 1868), of Berlin, explained the photographic reproduction of colour, so far as it had then been accomplished, by reference to stationary light waves. But no definite proof of their production had been brought forward. A few years ago Hertz demonstrated objectively the electromagnetic waves whose existence had been foretold by Maxwell's genius; and with suitable apparatus stationary electric waves are now almost as readily made evident as are those of sound. Hertz's brilliant success stimulated his fellow countryman, Otter Wiener, to undertake the apparently hopeless task of producing and studying stationary light waves. Wiener's admirable work (*Wiedemann's Annalen*, Band xl. 1890, p. 203) excited great interest on the continent of Europe, but it has been singularly neglected in England and America. It is worth much more than a passing notice.

Assume a plane silvered mirror upon which a bundle of rays of monochromatic light fall normally so as to be reflected back upon its own path. The superposition of reflected and direct waves causes a system of stationary waves, but under ordinary conditions these are wholly imperceptible. The nodes are formed upon a series of planes obviously parallel to the reflecting plane at successive distances of a half wave-length. If now we consider a plane oblique to the mirror, it will cut these successive nodal planes in parallel lines, whose distance apart will be greater in proportion as the oblique plane approaches parallelism to the mirror. Although a half wave-length of violet light is only $\frac{1}{5000}$ of a millimetre, it is easy to conceive of the cutting plane forming so small an angle with the mirror that the distance between the parallel nodal lines shall be a thousand times a half wave-length. Such would be the case if the inclination of the cutting plane is reduced to a little less than four minutes of arc. The nodal lines would be $\frac{1}{5}$ of a millimetre apart, and readily capable of resolution if their presence can be manifested at all. Imagine a very thin transparent photographic film to be stretched along the oblique cutting plane, and developed after exposure to violet light as nearly monochromatic as possible. Then the developed negative should present a succession of parallel clear and dark lines, corresponding to nodal and anti-nodal bands along the oblique plane, the photographic effect being annihilated along an optical nodal line.

The realisation of a photographic film thin enough for such an experiment is quite conceivable when we remember that under the hammer gold is beaten into leaves so delicate that 8000 of them would be required to make a pile one millimetre thick. By electrochemical deposit, Outerbridge (*Journal of the Franklin Institute*, vol. ciii. p. 284, 1877) has made films of gold whose thickness is only $\frac{1}{1000000}$ of a millimetre, or $\frac{1}{80}$ of a wave-length of sodium light. Wiener obtained a perfectly transparent silver chloride film of collodion, whose thickness was about $\frac{1}{30}$ of a wave-length of sodium light. This was formed on a plate of glass and inclined at a very small angle to a plane silvered mirror which served as reflector. From an electric arc lamp the light was sent through an appropriate slit and prism, so that a selected spectral band of violet fell normally on the prepared plate in the dark room. The developed negative presented the alternate bands, in perfectly regular order, more than a half millimetre apart. Various tests were applied to guard against error in interpretation, and the existence of such stationary waves was proved beyond all doubt.

These waves, moreover, when polarised light was employed, furnished the means of determining the direction of vibration with relation to the plane in which the light is most copiously reflected when incident at the polarising angle, and thus of subjecting to experiment the question as to whether the plane of vibration is coincident with this plane of polarisation or is perpendicular to it. The former of these views was held by Neumann and MacCullagh, the latter by Fresnel. Let a beam of polarised light fall upon the mirror at an angle of about 45°. If the vibrations in the incident beam are parallel to the mirror, and hence perpendicular to the plane of polarisation, those of the reflected and incident beams will be parallel to each other, and hence capable of interference. But if the vibrations of the incident beams are in a plane identical with that of incidence, and hence in the plane of polarisation, the vibrations of incident and reflected beams are in mutually perpendicular planes, and hence cannot interfere. Wiener obtained interference fringes when the light was polarised in the plane of incidence, while the polarised in the plane perpendicular to this gave no trace of interference. The theory of Fresnel was thus confirmed experimentally. Again, the familiar phenomenon of Newton's rings shows us that on changing media there is a change of phase of the incident light, else the central spot where the two surfaces come into optical contact would be white instead of black. But there has been difference of opinion as to whether this change of phase occurs at the upper surface of the air film, where the light passes from glass to less dense air, or at the lower surface where it passes from air to more dense glass. In the latter event, there should be a node at the reflecting surface. Replacing the silvered plane surface by a lens in contact with the photographic film, Wiener obtained circular fringes with no photographic action, at the centre, showing the nodal point to be at the point of contact, and thus again confirming the theory of Fresnel.

COLOUR PHOTOGRAPHY.

The conditions being now specified under which stationary light waves are produced, let us imagine common instead of monochromatic light to be transmitted normally through a transparent sensitive film. Then a variety of stationary interference planes are produced. This is the underlying principle of the process employed by Lippmann in Paris, who, in 1892 (*Comptes rendus*, t. cxiv. p. 961, and t. cxv. p. 575), succeeded in obtaining a photograph of the solar spectrum in natural colours. Upon a surface backed with a reflecting mirror of mercury is a silver bromide albumen film, which has been treated with one or more aniline dyes to render it equally sensitive to waves of long and short period. After exposure and development the natural colours are manifested with brilliancy. Apart from the fundamental principle already expressed, it can scarcely be said that the *rationale* of the process has yet been very fully and clearly explained. Lippmann recognises the stationary wave systems, with maxima and minima of brightness in the film and corresponding maxima and minima of silver deposit. If the incident light is homogeneous, a series of equidistant parallel planes of equal photographic efficiency are produced in the film. If the plate after development is illuminated with white light, then to every point within the film there comes from below a certain amount of reflected energy which is a continuous periodic function of the distance from the reflecting surface. The total reflected light of any colour becomes then represented by the integral of this periodic function for the entire thickness of the layer. The solution of this integral brings the result that the intensity of the reflected ight decreases with increasing thickness of the layer, approaching zero as a limit, so long as this light is of different wave length from the homogeneous light employed for illumination of the plate. Only light of the same wave-length, or of an entire multiple of this, maintains a finite value. A similar consideration applies to each of the hues composing white light. By such mathematical considerations Lippmann (*Journal de Physique*, p. 97, 1894) reaches the conclusion that the light reflected from the plate must have exactly the same relations of wave-length as that with which the plate was illuminated.

For the Lippmann photographs, which at first required a very

long exposure, and could even then be satisfactorily viewed at only a single definite angle, it is now claimed that an exposure of only a few seconds is needed, and that the colours are visible at all angles of incidence so long as the plate is moist (*Journal de Physique*, p. 84, 1894). But, like the daguerreotypes of fifty years ago, they are incapable of multiplication, and great as is the scientific interest connected with them, it seems scarcely probable that they can long continue to hold an important place practically. The problem of ascertaining definitely the cause of the return of a colour the same as that which falls upon a given surface may seem to be solved mathematically, but the mastery of the physical conditions required to produce a single coloured negative, from which may be had any desired number of positives with varied hues accurately reproduced, is still in the future. From the very nature of stationary light waves it does not appear probable that the Becquerel method as improved by Lippmann will give the means of multiplying copies of a single picture. Wiener has lately published an elaborate research upon this subject (O. Wiener, *Wiedemann's Annalen*, pp. 225-281, June 1895), in which he recognises the necessity for the employment not of interference colours but rather of what he calls body colours (Körperfarben) due to chemical modification of the reflecting surface. M. Carey Lea (*American Journal of Science*, p. 349, May 1887), in 1887 obtained a rose-coloured form of silver photochloride which "in the violet of the spectrum assumed a pure violet colour, in the blue it acquired a slate blue, in green and yellow a bleaching influence was shown, in the red it remained unchanged." But in the absence of any means of fixing these colours, a promising prospect brings disappointment.

While it is abundantly possible that coloured illumination upon suitable colour-receptive materials can give rise to similar body colours, we are still far from having these materials under control. There seems at present to be greater promise in another and quite different application of optical principles. The suggestion appears to have been first named by Maxwell (Royal Institution Lecture, May 17, 1861) in 1861 that photography in colours would be possible if sensitising substances were discovered, each sensitive to only a single primary colour. Three negatives might be obtained, one in each colour; and three complementary positives from these, when superposed and carefully adjusted, would present a combination that includes all the colours of nature. In 1873 H. W. Vogel in Berlin discovered that silver bromide, by treatment with certain aniline dyes, notably eosine and cyanine blue, can be made sensitive to waves of much longer period than those hitherto effective in photography. In 1885 he proposed to sensitise plates for each of a number of successive regions in the spectrum, and to make as many complementary pigment prints as negatives, which should then be superimposed. This somewhat complicated plan proved difficult in practice. In 1888 F. E. Ives (*Journal* of the Franklin Institute, January 1889), of Philadelphia, adopting the more simple Helmholtz-Maxwell modification of Young's theory of colour, applied it to the preparation of suitable compound colour screens which were carefully adjusted to secure correspondence with Maxwell's intensity curves for the primary colours. The result was a good reproduction of the solar spectrum. But to reproduce the compound hues of nature it is necessary specially to recognise the fact that although the spectrum is made up of an infinite number of successive hues, the three colour sensations in the eye are most powerfully excited by combinations rather than by simple spectral hues. Thus according to Maxwell's curves, the sensation of red is excited more strongly by the orange rays than by the brightest red rays, but the green sensation is excited at the same time. This fact has to be applied in the preparation of the negatives, while images or prints from these must be made with colours that represent only the primary colour sensations. Properly selected colour screens must therefore be used for transmission of light to plates sensitised with suitable aniline dyes; and the adjustment of ratios with this end in view is not easy. But it has been successfully accomplished. From three negatives thus made, each in its proper tint, positives are secured; and these are projected, each through its appropriate colour screen, to the same area upon a white screen. The addition of lights thus sent from the triple lantern gives the original tints with great fidelity.

Mr. Ives has devised a special form of camera by which the three elementary negatives are taken simultaneously, and also an instrument, the photochromoscope, in which a system of mirrors and lenses brings to the eye a combination similar to that projected with the triple lantern. A double instrument of this kind forms the most perfect type of stereoscope, bringing out with great vividness from the prepared stereographs the combined effect of colour, form and binocular perspective. It is only within the past year that these improvements have been perfected. By further application of the same principles, Mr. Ives has produced permanent coloured prints on glass, which do not require to be examined by the aid of any instrument. Each of these negatives is made with a coloured screen which transmits tints complementary to those which it is desired to reproduce. The three gelatine films are soaked in aniline dyes of suitable tint, and superimposed between plates of glass. When viewed as a transparency such a print gives a faithful reproduction of the natural colours.

The problem of colour reproduction is thus solved, not indeed so simply, but more effectively, than by the method of interference of light, or by those body-colour methods that have thus far been applied. To the imaginative enthusiasts who are fond of repeating the once novel information that "electricity is still in its infancy," it may be a source of equal delight to believe that photography in colours, a yet more delicate infant, is soon to take the place of that photography in light and shade with which most of us have had to content ourselves thus far; but so long as an instrument is needed to help in viewing chromograms, the popular appreciation of these will be limited. We may take a lesson from the history of the stereoscope. Yet it is gratifying to recognise the great impetus that this beautiful art has received during the last few years. We may quite reasonably expect that the best is yet to come, and that it will have an important place among the future applications of optical science.

THE INFRA-RED SPECTRUM.

Among the splendid optical discoveries of this century, probably the most prominent are photography and spectrum analysis, each belonging jointly to optics and chemistry. Photography was at first supposed to be concerned only with the most refrangible rays of the spectrum, but Abney and Rowland have photographed considerably below the visible red. Beyond the range thus attained qualitative knowledge was secured by Herschel, Becquerel, Draper, Melloni, Müller, Tyndall, Lamansky and Mouton. But our quantitative knowledge of this region began with the invention and use of the bolometer by Langley ("Selective Absorption of Solar Energy," *Am. Journal of Science*, March 1883, p. 169), whose solar energy curve has been familiar to all physicists during the last dozen years. During this interval the bolometer has been used with signal success by Ångström, Rubens, Snow and Paschen, who have made improvements not only in the instrument itself but in the delicacy of its necessary accompaniment, the galvanometer. The work of Snow (*Physical Review*, vol i. pp. 28 and 95), particularly, on the infra-red spectra of the voltaic arc and of the alkalies, and that done by him in conjunction with Rubens (*Astronomy and Astrophysics*, March 1893, p. 231), on refraction through rock-salt, sylvite, and fluorite, exhibited the capacities of the bolometer even better perhaps than Langley's previous work on the sun. But more recently with the collaboration of several able assistants, and more particularly the great ingenuity and mechanical skill of Wadsworth, the sensitiveness of Langley's galvanometer has been so exalted, and the bolometer connected in such manner with photographic apparatus as to make it an automatically controlled system, by which an hour's work now brings results superior in both quantity and quality to what formerly required many weeks or even months (Langley, "On Recent Researches in the Infra-red Spectrum": Report of Oxford Meeting of British Association, 1894). Not only is an entire solar energy curve now easily obtained in a single day, but even a succession of them. It becomes thus possible by comparison to eliminate the effect of temporary disturbing conditions, and to combine results in such a way as to represent the infra-red cold bands almost as accurately as the absorption lines of the visible spectrum are indicated by use of the diffraction grating. It will undoubtedly become possible to determine in large measure to what extent these bands are due to atmospheric absorption, and which of them are produced by absorption outside of the earth's atmosphere.

With the diffraction grating, supplemented by the radiomicrometer, Percival Lewis (*Astrophysical Journal*, June 1895, p. 1, and August 1895, p. 106), has recently investigated the infra-red spectra of sodium, lithium, thallium, strontium,

calcium and silver, attaining results which accord well with the best previously attained by those who had employed the bolometer, and which demonstrate the exceeding delicacy of the radiomicrometer as an instrument of research.

The Visible Spectrum.

To follow out all the applications of the spectroscope that have resulted in recent additions to our knowledge would carry us far beyond the scope of a single paper. It is possible only to make brief mention of a few.

For a number of years Rowland (*ibid.*, January to August 1895) has been investigating the spectra of all the chemical elements, photographing them in connection with the normal solar spectrum, and reducing them to his table of standards, which is now accepted everywhere. The work is of such magnitude that years more must elapse before its completion. It now includes all wave lengths from 3722 to 7200, and of these the list already published extends as far as wave-length 5150, or from ultra-violet nearly to the middle of the green.

Through the spectroscope chiefly has been established during the present year the discovery of the new atmospheric element, argon, by Lord Rayleigh and Prof. Ramsay (*Proc. Royal Society*, January 31, 1895); its remarkable property of green fluorescence when the electric spark is passed through it in presence of benzene, by Berthelot and Deslandres (*Comptes rendus*, June 24, 1895); and its association in meteoric iron and various minerals with helium, now proved to be a terrestrial as well as solar element, by Ramsay (NATURE, April 4, May 16, July 4 and 25, 1895), Crookes, Lockyer, and others.

With the diffraction spectroscope Rydberg (*Wiedemann's Annalen*, 1893–94) and Kayser and Runge (*ibid.*, 1888–95) have discovered interesting relations among the spectral lines of a large number of terrestial elements, arranging them into series whose distribution manifests chemical relationship quite analogous to that indicated in Mendelejeff's periodic law.

By photographing the spectrum of Saturn's rings and noting the relative displacement of the different parts of a spectral line, Keeler (*Astrophysical Journal*, May 1895, p. 416) has obtained a beautiful direct proof of the meteoric constitution of these rings, a confirmation of the hypothesis put forth by Maxwell in 1859, that the outer portion of the rings must revolve more slowly than the inner portion, and yet not satisfy the conditions of fluidity. His work has been repeated and confirmed by Campbell (*ibid.*, August 1895, p. 127) at the Lick Observatory.

The spectroheliograph devised by Hale (*Astronomy and Astrophysics*, March, 1893, p. 256) has enabled him to photograph, on any bright day, not only the solar photosphere and spots, but also the chromosphere and protuberances. He has made some remarkable attempts with this instrument to photograph the corona without an eclipse, unsuccessfully thus far, but not without promise of future success.

Polarised Light.

In the domain of polarised light, there have been several noteworthy recent researches. Nichols and Snow (*Philosophical Magazine* (5), vol xxxiii. p. 379) have shown that calcite, though readily transparent for the brighter rays of the spectrum, rapidly diminishes in power of transmission for waves of short period, so that for the extreme violet this power is scarcely half so great as for the yellow. The transmissive power of this crystal for the infra-red rays, between the wave-length limits of 1 micron and 5·5 microns, has been investigated with the bolometer by Merritt (*Physical Review*, May–June 1895, p. 424) who reaches the interesting result that the transmission curve for the ordinary ray is wholly independent of that for the extraordinary, the absorption being in general much greater for the former. Several sharp absorption bands are found for each ray. For radiations whose wave-length exceeds 3·2 microns, the absorption of the ordinary ray is almost complete, so that calcite behaves for such radiation just as tourmaline does for the rays of the visible spectrum. The independence of the two transmission curves is found to exist also for quartz and tourmaline, these curves for the latter crossing each other twice in the infra-red region.

The application of polarised light to the investigation of internal stress in transparent media was made more than forty years ago by Wertheim (*Comptes rendus*, 32, p. 289, 1851), who demonstrated that the retardation of the rays is proportional to the load. An extended series of such experiments has been lately made in America by Marston (*Physical Review*, September, October, p. 127, 1893) who, besides confirming Wertheim's conclusion, shows that, "for small strains at least, the colours seen in a strained glass body, when polarised light is passed through it in a direction parallel to one of the axes of strain, are measured by the algebraic difference of the intensities of those two principal strains whose directions are perpendicular to the direction of the polarised light."

A new substance with double rotatory power, like quartz, has been discovered by Wyrouboff (*Journal de Physique* (3), 3, 452, 1894), the neutral anhydrous tartrate of rubidium, which is unique in one respect. The rotatory power of the substance in the crystalline state becomes reversed in solution. This wholly new phenomenon introduces some perplexity in connection with certain molecular theories that have been formulated to account for double rotatory power.

Crehore (*Transactions* of the American Institute of Electrical Engineers, October 1894, p. 91) has ingeniously applied Faraday's principle of electro-magnetic rotation of the plane of polarisation in carbon bisulphide to the photographing of alternate current curves. Every variation in the magnetic field causes variation in the amount of light transmitted through a pair of crossed Nicol prisms. The combination becomes a chronograph with an index as free from inertia as the beam reflected from a galvanometer mirror. The same instrument has been applied to measurement of the velocity of projectiles (*Journal of the United States Artillery*, p. 409, July 1895), with results of exceeding interest to the student of gunnery.

Physiological Optics.

The temptation to dilate upon recent progress in physiological optics has to be resisted. The revision of Helmholtz's great book on this subject was interrupted by the death of the distinguished author, but the last part is now approaching completion under the care of his pupil, Arthur König, who, in conjunction with Diederici, has done much important work in this domain. The selection of hues for the three primary colour sensations has been slightly modified. Young selected the two extremes of the spectrum, red and violet, together with green, which is about midway between them. The hues now accepted by Helmholtz and those who follow his lead, including the great majority of physicists, are a highly saturated carmine red, an equally saturated ultramarine blue, and a yellowish green, corresponding somewhat to that of vegetation. The red and blue agree with those previously determined by Hering, but the rivalry between the two schools on the subject of colour sensation continues, and perhaps will last through a period commensurate with the difficulty of devising crucial experiments.

Independent theories of colour sensation have been brought out by Mrs. Franklin (Christine Ladd Franklin, "Eine neue Theorie der Lichtempfundungen," *Zeitschrift für Psychologie und Physiologie der Sinnesorgane*, 1892) in America, and by Ebbinghaus ("Theorie des Farbensehens," *ibid.*, 1893) in Germany. The former particularly is worthy of much more extended notice than can here be given. It may perhaps be quite properly called a chemical theory of vision. Light is always bringing about chemical changes in external objects, and the eye is the one organ whose exercise requires the action of light, while such chemical action is implied in the performance of most of the bodily functions, such as the assimilation of food and the oxidation of the blood. The bleaching action of light upon the visual purple, which is continually formed on the retina, has been known ever since the discovery of this in 1877 by Kühne, who secured evanescent retinal photographs in the eyes of rabbits. Mrs. Franklin considers that light sensation is the outcome of photo-chemical dissociation of two kinds of retinal molecules that she denominates grey molecules and colour molecules, of which the latter arise from the grey molecules by differentiation in such a way that the atoms of the outer layer group themselves differently in three directions, and the corresponding action of light of proper wave-length gives rise to the three fundamental colour sensations. She develops the theory with much skill, applying it particularly to the phenomena of retinal fatigue and colour blindness. To the objection that there is no direct proof of the existence of the assumed grey and colour molecules, it may be answered that Helmholtz himself fully recognised the uncertainty of the assumption that three different sets of nerves respond to the three fundamental colour sensations, and he admitted that these may be only different activities in the same retinal cone. The supposition of three adjacent cones, responding respectively to

the three fundamental sensations, is made only for the sake of greater convenience in discussion.

Indeed there is still much for us to learn regarding the nature of colour sensation. Among the yet unexplained phenomena are those of simultaneous colour contrast. The fact that a small brightly-coloured area on a grey background appears surrounded by its complementary tint is familiar enough. For its explanation it has been common to assume that there is unconscious motion of the observer's eyes, incipient retinal fatigue, an error of judgment, or fluctuation of judgment. This has been tested by A. M. Mayer (*American Journal of Science*, July 1893), who ingeniously devised methods for showing these contrast phenomena on surfaces large enough to match the colours with those of rotating colour discs, and thus to arrive at quantitative statements of their hues. When viewed through a small opening in a revolving disc the subjective contrast colour was unmistakably perceptible when the duration of passage of the opening was less than $\frac{1}{1000}$ of a second. The same effect was obtained in a dark room with instantaneous illumination of the coloured surface by the strong spark of an electric influence machine. The duration of illumination is thus almost infinitestimal, certainly not more than $\frac{1}{1000000}$ of a second. The hypothesis of fluctuation of judgment is thus shown to be wholly untenable. I have performed most of these experiments, either with Prof. Mayer or separately, and my testimony can therefore be united with his. The case is quite analogous to that of the perception of binocular relief, which was once explained as the product of a judgment, but was found to be always possible with instantaneous illumination. Prof. Mayer has devised a disc photometer based on colour contrast, with which the error of a single reading was found much less than with the Bunsen photometer.

The rotating colour disc has been applied by O. N. Rood (*American Journal of Science*, September 1893) to the determination of luminosity independently of colour, by taking advantage of the flickering appearance on a rotating disc upon which two parts have different reflecting powers. An extreme case of this is that of a white sector upon a black disc. At a certain critical speed the retinal shock due to momentary impression by white light becomes analysed into the subjective impression of spectral colours, the duration of the retinal sensation varying with the wave-length of the incident light. The law of this variation has been studied by Plateau ("Dissertation sur quelques propriétés des impressions produits par la lumière sur l'organe de la vue," Liège, 1829), Nichols (*American Journal of Science*, October 1884), and more recently with much precision by Ferry (*ibid.*, September 1892), who showed that retinal persistence varies inversely as the logarithm of the luminosity. For a given source of light separated into its spectral components, the yellow is the brightest. For this hue accordingly the retinal impression is shortest, and for violet it is longest.

Under appropriate conditions the after-effect on the retina has a certain pulsatory character, as first noted by C. A. Young (*Philosophical Magazine*, vol. xliii. p. 343, 1872) in 1872, and carefully studied within the last few years by Charpentier ("Oscillations rétiniennes," *Comptes rendus*, vol. cxiii. p. 147, 1891) in France, and Shelford Bidwell ("On the Recurrent Images following Visual Impressions," *Proc. Royal Society*, March 27, 1894) in England. A disc with properly arranged black and white sectors, if brightly illuminated and looked at while revolving at a moderate rate, becomes apparently coloured, just as a momentary glance at the sun causes the perception of a succession of subjective spectral hues which may last a number of seconds. The phenomenon in relation to the disc was known as early as 1838 (Fechner, *Poggendorff's Annalen*, 1838), and explained by Rood (*American Journal of Science*, September 1860) in 1860. The re-discovery of what has been long forgotten arouses all the interest of novelty. The "artificial spectrum top," devised by Benham (NATURE, November 29, 1894, p. 113) last autumn, excited interest on two continents, and was promptly copy righted by a prominent firm of opticians (*ibid.*, March 14, 1895, p. 463) in England. It would perhaps be equally enterprising to copyright the solar spectrum.

The limits of a single address forbid my touching upon the large and practically important subject of colour blindness. Indeed, in both physical and physiological optics much has been omitted that is abundantly worthy of attention. In behalf of my hearers it may be wise to take heed, once more, of the fate of Tarpeia, who was overwhelmed with the abundance of her reward.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Technical Education Board of the London County Council has just awarded 278 minor scholarships, viz. 178 to boys and 100 to girls in Elementary Schools; 334 scholarships of the same class were awarded last spring, upon the results of examination, so that altogether the number awarded by the Board in 1895 was 612.

AT a meeting of the Fellows of the Royal College of Surgeons, held on Thursday last in the theatre of the college, a resolution was carried, "that, in the opinion of the Fellows of this college, women should be admitted to the diplomas of the college," forty-seven Fellows voting for the resolution and only ten against. The Fellows alone form the electorate who vote for election to the council, and the effect of this resolution will probably cause the council (who are understood not to be unwilling) to open the examinations to women candidates. At a mixed meeting of Fellows and members, called by the President last November to consider an application from the Dean of the London Medical School for Women for this privilege, Mr. Clement Lucas's proposal to the same effect was negatived by the narrow majority of ten in a house of over a hundred.

IN connection with the new Technical Institute recently opened at Wandsworth, the London *Technical Education Gazette* recalls the interesting fact that the first technical school in this country was opened in Wandsworth. The third annual report issued by the Science and Art Department, in 1856, gives an interesting account of this first technical school, which was called the Wandsworth Trade School. The curriculum included partly subjects of general instruction and partly courses of trade instruction classified under three heads, according as they had relation to (1) the building trades, (2) the mechanical and engineering trades, and (3) the chemical and manufacturing trades. The new Technical Institute will, it is hoped, revive the traditions established by the pioneer school of 1856. In addition to an equipment grant of £500, the Technical Education Board has agreed to contribute £1000 to the maintenance of the institute for the current year, apart from any grants which it may make for the maintenance of the technical day school.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, vol. ii. No. 2, November 1895.—Concerning Jordan's linear groups, is a paper by Prof. E. H. Moore, which was read before the Society in August last. It is a continuation of a paper read in November 1894, entitled "The group of holoedric transformation into itself of a given group" and is an exhaustive one supplemented by numerous bibliographical details.—Prof. A. S. Hathaway presented, at the same meeting in August, an elementary proof of the quaternion associative principle. Hamilton in his "Elements" writes: "The *associative principle* of multiplication may also be proved without the distributive principle, by certain considerations of *rotations of a system*, on which we cannot enter here." This note states that it is easy to see that such a proof is possible; but the details of it could not have presented themselves to Hamilton in an elementary form, or he would have seen that it was just the demonstration for which he was looking, simple in character, and direct in its application. We are not sure that we have not seen a proof somewhat similar to the Professor's, but we cannot recall it to our recollection. The proof given is a simple one.—The next article is a paper read at the October meeting of the Society, entitled "Moral Values," by Mr. R. Henderson. The author reminds us that the question of moral values in connection with the theory of probability has given rise to great diversity of opinion among mathematicians, and that Bertrand, in his classical work, dismisses it with contempt. More than the usual space is devoted to the notes and new publications.

American Meteorological Journal, December 1895.—Psychrometer studies, by Dr. Nils Ekholm. This article chiefly refers to the peculiar action of the wet-bulb thermometer near the freezing point of water. The author's observations and other investigations show that in an air saturated with water-vapour, the ice-covered bulb reads higher than the water-covered one, which, under those conditions, reads exactly as the dry bulb. These results are explained by Prof. W. Ramsay's experiments, which prove that there is a difference in the tension of water-

vapour and ice-vapour at the same temperature.—Meteorology as a University course, by R. de C. Ward, Instructor in Meteorology in Harvard University. The author's aim is to show the need of more instruction in meteorology, and to emphasise the fact that instruction is needed in general, rather than in the higher mathematical and physical meteorology; while the investigation of problems in the latter branches should be undertaken by eminent physicists who are fitted to do work of such an advanced character. The author considers that, at the present time, Germany takes the lead in the teaching and in the research of meteorology.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 12, 1895.—"Researches on the Structure, Organisation, and Classification of the Fossil Reptilia. Part X. On the complete Skeleton of an Anomodont Reptile (*Aristodesmus Rütimeyeri*, Wiedersheim), from the Bunter Sandstone of Reihen, near Basel, giving new Evidence of the Relation of the Anomodontia to the Monotremata." By H. G. Seeley, F.R.S.

The author has examined the fossil described by Dr. Robert Wiedersheim in 1878 as *Labyrinthodon Rütimeyeri*. The bones are differently interpreted:—

The reputed humerus is the interclavicle.

The reputed right and left coracoids are the pre-coracoid and coracoid of the right side.

The author regards the Labyrinthodont osteology as demonstrating close relationship with Ichthyosauria and Anomodontia. The group forms a branchiate division of the reptilian class.

The fossil now named *Aristodesmus* is identified as an Anomodont reptile chiefly on the basis of resemblances to *Procolophon* and *Pareiasaurus*.

The teeth are in sockets placed obliquely. The proportions of the vertebral column are those of *Echidna*, though the transverse processes are longer. The ribs are those of a Monotreme. The shoulder girdle resembles *Procolophon*, and the humerus does not show the peculiar lateral curvature seen in Monotremes. The ulna gives no evidence of an olecranon process; the pelvic bones are without acetabular or obturator perforations, are not anchylosed together, and the ilium is not expanded transversely. The femur is more slender than in *Echidna*. The fibula is prolonged proximally beyond the stout tibia, round which it may rotate. The proximal row of the tarsus is one large bone, the blended astragalus and os calcis.

Monotreme mammals make a close approximation to this fossil and other Anomodontia. A group *Theropsida* may be made to include Monotremata and Anomodontia. *Ornithorhynchus* shows pre-frontal and post-frontal bones, and has the malar formed as in Anomodonts.

Aristodesmus is placed in the Procolophonia, which has two occipital condyles, with the occipital plate vertical, without lateral vacuities; and has the shoulder girdle distinct from Pareiasauria in the separate pre-coracoid extending in advance fo the scapula.

PARIS.

Academy of Sciences, December 30.—M. Marey in the chair.—Development of the lymphatic vessels, by M. L. Ranvier. The author has examined the development of the lymphatic vessels in the embryo of the pig. By examining the mesentery, hardened in osmic acid and stained with picro-carmine, no lymphatic vessels can be observed in embryos of less than 9 cm. in length, the first signs appearing in those of 10 cm. The conclusion is drawn that the lymphatic system may be considered as an immense vascular gland, having its embryological origin in the venous system, and throwing its secretory product, the lymph, into the veins.—On the second scientific expedition of the *Princesse Alice*, by Albert First, Prince of Monaco. (See pp. 223-225.)—Note on the history of seas, by M. Suess. From the results of geological explorations, by MM. Mojsisovics, Waagen, and Diener, undertaken with special reference to the Trias formation, the conclusion is drawn that at that period the Pacific Ocean possessed two great branches—one (the Arctic branch) stretching over Eastern Siberia as far as Spitzbergen, the other across Central Asia and the Alps up to the Western Mediterranean.—On the acoustic analysis of mixtures of two gases of different densities, by M. E. Hardy. The method was capable of detecting one volume of illuminating gas in 1000 volumes of air.—Observations, made at the observatory of Algiers, of Brooks' and Perrine's comets, by MM. Rambaud and Sy.—Observations of Faye's comet and a minor planet, made at the Toulouse Observatory, by M. F. Rossard.—Observations of the sun, made at the observatory of Lyons, by M. J. Guillaume.—On some problems in variations, by M. G. Kœnigs.—On the summation of divergent series, by M. E. Borel.—On a new transformation of Taylor's theorem, by M. N. U. Bougaief.—On the unicursal varieties of three dimensions, by M. Antonne.—New properties of the cathode rays, by M. Jean Perrin. According to the views of Goldstein, Hertz, and Lenard, the cathode rays are due, like light, to a vibration of the ether; whilst Crookes and J. J. Thomson prefer to attribute the phenomena to matter charged negatively travelling with a high velocity. All the results of the extremely ingenious experiments of M. Perrier tend to show that the latter view is the correct one.—Observations on the zodiacal light, made at the observatory of the Pic du Midi, by M. E. Marchand.—On the elliptic refraction of quartz, by M. G. Quesneville. It is shown by a recalculation of Jamin's experiments, that the formula used by Jamin, calculated from Airy's theory, gives quite erroneous results in the neighbourhood of the axis.—The position in the solar spectrum of the calorific maximum, by M. Aymonnet. A comparison of the results obtained by various workers in this subject, shows that the position of this maximum depends not only on the composition of the prism, but also on the other parts of the spectroscope which reflect or transmit the ray. The continual variation in the intensity of the solar radiation is also a source of grave error in these measurements.—On the mechanical production of extreme temperatures, by M. E. Solvay. Remarking on the liquefaction of air in quantity recently achieved by M. Linde, M. Solvay observes that he used the same principle, the successive expansions of the same quantity of gas, in 1886, but, having imposed on himself as practical conditions that the pressure must not exceed 5 atmospheres, and not take more than 15-horse power, the lowest temperature he actually reached in this way was $-95°$. It is further pointed out that inversely the same principle would serve to reach extremely high temperatures, were it not for the fact that these can be more easily attained by electrical means.—On the combustion of acetylene, by M. H. Le Chatelier. Mixtures of acetylene with air containing less than 7·7 per cent. of acetylene, burn completely to water and carbon dioxide, for proportions of acetylene between 7·7 per cent. and 17·4 per cent., the products consist of water, carbon monoxide and dioxide, water, and hydrogen, in mixtures containing more acetylene than this free carbon and unburnt acetylene are found. With oxygen, mixtures containing anything between 2·8 per cent. and 93 per cent. of acetylene will catch fire; with air the limits are 2·8 per cent. and 65 per cent. In tubes, these limits are narrowed down, until in tubes of 0·5 m.m. diameter or less it is impossible to propagate a flame.—On the fixation of nitrogen by the metals of the alkaline earths, by M. L. Maquenne. After referring to his earlier work on this subject, the author describes a simple lecture experiment illustrating the ease with which nitrogen is absorbed. A mixture of lime and magnesium powder heated in a hard glass tube over a Bunsen burner will, in five minutes, absorb 96 per cent. of a confined volume of air.—On crystallised titanium and the combinations of titanium and silicon, by M. L. Levy. A silicide of the composition Ti_2Si has been isolated.—On the rotatory power of rhamnose in a state of superfusion, by M. D. Gernez. The rotatory power of fused rhamnose diminishes regularly with rise of temperature; at 100° it is only 61 per cent. of its value at 0°, and is in all cases less than that deduced from the rotatory power of its solutions.—On some dithiazolic derivatives, by M. C. Lauth.—Syntheses of acid chlorides and amide hydrochlorides, by M. A. Colson. The following reaction is found to occur.

$$RCN + R^1.CO_2H + 2HCl = R.CO.WH_2.HCl + R^1COCl.$$

when R, R^1 may be methyl or ethyl. This reaction is suggested as a method for preparing acid chlorides without the use of the phosphorus chlorides. If the acid is replaced by its anhydride the yield is improved.—Action of the halogens upon formaldehyde, by M. A. Brochet. In the case of chlorine, the primary reaction is $CH_2O + Cl_2 = CO + 2HCl$. The $COCl_2$, previously observed, is a secondary product.—On essence of lemon, by

MM. P. Barbier and L. Bouveault.—Study in germination, by M. J. de Rey-Pailhade.—On the simultaneous determination of the mineral and organic acidity in the juice of the beetroot, by M. D. Sidersky. Advantage may be taken of the indifference of Congo-red paper to the organic acids, but a simpler method is to use a colouring matter present in the juice itself.—The origin of the three-colour theory of the optic nerve, by M. J. P. Durand. A recognition of the work of Thomas Young.—On the influence of lecithin on the growth and multiplication of organisms, by M. B. Danilewsky.—Comparative study of the buccal mass of gasteropods, by M. A. Amaudrut.—Cephalopods from the stomach of a cachalot, caught at the Azores, by M. L. Joubin.—Some effects of the synodic revolution of the moon on the distribution of atmospheric pressures in the autumn season, by M. A. Poincaré.—On a meteor observed in Algeria, December 14, 1895, 10h. 15m. p.m., by M. J. Triboulet.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, JANUARY 9.

SOCIETY OF ANTIQUARIES, at 8.30.
MATHEMATICAL SOCIETY, at 8.—On a certain Ternary Cubic: Prof. Lloyd Tanner.—Further Communication on Boltzmann's Minimum Function: S. H. Burbury, F.R.S.—Examples illustrating Lord Rayleigh's Theory of the Stability or Instability of certain Fluid Motions: A. E. H. Love, F.R.S.
ROYAL INSTITUTION, at 3.—Sound, Hearing, and Speech: Prof. McKendrick, F.R.S.

FRIDAY, JANUARY 10.

MALACOLOGICAL SOCIETY, at 8.—List of South Australian Pleurotomidæ with Descriptions of New Species: G. B. Sowerby.—Descriptions of New Land Mollusca from New Zealand and Macquarie Island: Henry Suter.—The Genus Hyalimax, or a near Ally (Neohyalimax), in Brazil: Dr. H. Simroth.—On a Collection of Slugs from the Sandwich Islands: Walter E. Collinge.
ROYAL ASTRONOMICAL SOCIETY, at 8.
CLINICAL SOCIETY, at 8.30.

SATURDAY, JANUARY 11.

ASSOCIATION FOR THE IMPROVEMENT OF GEOMETRICAL TEACHING (University College), at 11.—At 2.—Business Meeting.—Geometrical Methods: Dr. Larmor.
ROYAL BOTANIC SOCIETY, at 3.45.

SUNDAY, JANUARY 12.

SUNDAY LECTURE SOCIETY, at 4.—Pasteur and his Work: Prof. Percy Frankland, F.R.S.

MONDAY, JANUARY 13.

MEDICAL SOCIETY, at 8.30.

TUESDAY, JANUARY 14.

ROYAL INSTITUTION, at 3.—The External Covering of Plants and Animals: its Structure and Functions: Prof. C. Stewart.
INSTITUTION OF CIVIL ENGINEERS, at 8.—The Sanitary Works of Buenos Ayres: Sewerage, Drainage, and Water-Supply: Hon. R. C. Parsons.
ZOOLOGICAL SOCIETY, at 8.30.—A Preliminary Revision and Synonymic Catalogue of the Hesperiidæ of Africa and the adjacent Islands, with Descriptions of some apparently New Species: Rev. W. J. Holland.—On a Collection of Butterflies obtained by Mr. R. Crawshay in Nyasaland between the Months of January and April, 1805: Dr. Arthur G. Butler.—On a Newly-discovered Modification of the Iris in the Eyes of certain of the Ungulata adapted for assisting Vision: Dr. G. Lindsay Johnson.
ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Astigmatism and a New Stigmatic Portrait Lens: H. L. Aldis.
ROYAL ASIATIC SOCIETY, at 3.
ROYAL MEDICAL AND CHIRURGICAL SOCIETY, at 8.30.

WEDNESDAY, JANUARY 15.

SOCIETY OF ARTS, at 8.—The Making of a Great University for London: Prof. Silvanus P. Thompson, F.R.S.
ENTOMOLOGICAL SOCIETY, at 8.—Annual Meeting.—Election of Council and Officers.—The Speculative Method in Entomology: Prof. Meldola, F.R.S., President.
ROYAL MICROSCOPICAL SOCIETY, at 8.—Annual Meeting.—Election of Council.—Address by the President, A. D. Michael.
ROYAL METEOROLOGICAL SOCIETY, at 8.—Annual General Meeting.
BRITISH ARCHÆOLOGICAL ASSOCIATION, at 8.

THURSDAY, JANUARY 16.

ROYAL SOCIETY, at 4.30.
LONDON INSTITUTION, at 6.—Experiments with Incandescent Lamps: Prof. Fleming, F.R.S.
LINNEAN SOCIETY, at 8.—On the Fistulose Polymorphinæ and the Ramulinæ: Prof. T. Rupert Jones, F.R.S., and F. Chapman.
SOCIETY OF ARTS, at 4.30.—The Shan Hills: their Peoples and Products: Colonel R. G. Woodthorpe, C.B., R.E.
SOCIETY OF ANTIQUARIES, at 8.30.
CHEMICAL SOCIETY, at 8.—The Acetylene Theory of the Luminosity of Hydrocarbon Flames: Prof. Vivian B. Lewes.—And other Papers.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Presentation of Premiums.—Inaugural Address of the President, Dr. John Hopkinson, F.R.S.
NUMISMATIC SOCIETY, at 7.

FRIDAY, JANUARY 17.

ROYAL INSTITUTION, at 9.—More about Argon: Lord Rayleigh.
QUEKETT MICROSCOPICAL CLUB, at 8.
INSTITUTION OF CIVIL ENGINEERS, at 8.—Iron Tunnels: W. O. Leitch.
EPIDEMIOLOGICAL SOCIETY, at 8.—Experiences in Relation to Cholera in India from 1842-79: Surgeon-General C. A. Gordon, C.B.

SATURDAY, JANUARY 18.

ROYAL INSTITUTION, at 3.—To the North of Lake Rudolf and among the Gallas: Dr. A. Donaldson Smith.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Annuaire pour l'an 1896, publié par Le Bureau des Longitudes (Paris, Gauthier-Villars).—Le Mouvement: E. J. Marey (Paris, Masson).—Principii della Teoria Matematica del Movimento dei Corpi: Prof. G. A. Maggi (Milano, Hoepli).—Elementary Treatise on Electricity and Magnetism: Profs. CONTENTS.

THURSDAY, JANUARY 16, 1896.

EUCLID AND HIS EDITORS.

Euclid's Elements of Geometry. Edited for the Syndics of the Press by H. M. Taylor, M.A. Books I.–VI., XI., XII. Pp. xxii + 658. (Cambridge: at the University Press, 1895.)

THE appearance of a school edition of "Euclid's Elements," published under the auspices of the Cambridge University Press, provokes reflections upon the strange position so long maintained in this country by Robert Simson's authorised version (so to speak) of the work of the Alexandrian geometer. For more than a hundred years the Simsonian text enjoyed an unchallenged supremacy; and not so very long ago any proposal to amend it, or to teach elementary geometry by means of some other book, was regarded as something very like profanity.

It is only in accordance with the nature of things that this professed veneration for Euclid should coexist with a profound ignorance of the real *Elements*, and of the other extant works of their author. To this day the reputation of Euclid is not unlike that of the wizard Virgil in the Middle Ages. Most educated Englishmen are quite unaware of the existence of those books of the Elements which are not read in schools; there is even a legend current in some quarters that they were destroyed in MS. by Euclid's wife! For the only good critical edition of Euclid's works (Heiberg's, in the Teubner Series) we must go to Germany; and it would be interesting to know how many English mathematicians are acquainted with the original text, and how many English scholars have had the curiosity to find out whether "parallel*o*piped" (rhyming with "biped," by the way) is vouched for by the Greek. To crown the absurdity, it is just that book of the Elements which is of greatest permanent value that, by common consent, is never read.

After all, the study of the real Euclid may very fitly remain the privilege of the minority; the really urgent need is that geometry should be taught rationally and effectively in our schools. Happily, we have outlived the glacial period which still prevailed in the early part of this century; and all good authorities are practically agreed upon the main lines of reform. The weight of opinion among experienced teachers seems still to be in favour of retaining at least the framework of the Elements, and of following, generally, Euclid's sequence of propositions. In favour of this course there is something to be said, independently of the base consideration of examination requirements. That there is a certain advantage in a recognised order of propositions will probably be admitted by most of those who have wandered in the chaos of geometrical conics; and with regard to Euclid's methods of proof, it is doubtful whether the various alternatives which have been suggested are really easier for a schoolboy to learn and understand. A beginner is very apt to appeal to his powers of intuition in a quite illegitimate way; and in trying to reproduce a proof which depends upon superposition or symmetry he often loses himself in a haze of words, and fails to give a sound demonstration. Proofs of this kind may very well be included, of course; but should not, we think, take the place of the more formal ones in the text.

Mr. Taylor's book is one of several which, while harmlessly masquerading as "editions" of Euclid, are really excellent treatises on elementary geometry, based upon the lines which Euclid has laid down. Signs of the wholesome reform that has taken place, meet the eye on every page. The antiquated terms, the clumsy repetitions, the tiresome rigmaroles of Simson's text are done away with; notes and explanations are given where necessary; additional propositions are introduced; and there is an abundance of exercises, carefully graduated, and properly distributed throughout the book, instead of being hidden away at the end of it. One of the extraordinary superstitions of former days was that nobody could do a geometrical deduction unless he had previously learnt three books of Euclid by heart; it is to be hoped that this ridiculous theory is at length abandoned. Some boys, of course, can never do a "rider," even the easiest; but those who have any capacity can be started successfully after learning the first five propositions, or even before.

School Euclids may be roughly divided into two classes, according as symbols of abbreviation are used or avoided. While such a notation as AB^2 for "the square on AB" is decidedly objectionable, the use of symbols of *mere* abbreviation is a matter of taste. Personally we detest them, and rejoice that they do not appear in Mr. Taylor's treatise. Brevity has been secured in the proper way, by a careful choice of words, and not by a host of contractions and ugly symbols for "circle," "parallelogram," and so on.

There are several attractive features in Mr. Taylor's book to which attention may be drawn. The selection of additional propositions is very good, and it is needless to say that the proofs given are very elegant. There is a most interesting collection of proofs of Pythagoras's theorem (i. 47); Ptolemy's theorem is proved by means of Book iii.; and Gergonne's construction for the circles touching three given circles, is to be found on p. 458. There are also sections dealing with poles and polars, coaxal circles, projective rows and pencils, Pascal's and Brianchon's theorems for the circle, centres of similitude, and inversion (including an account of Peaucellier's cell); besides this, there is a long supplement to Book xi., which discusses, *inter alia*, properties of tetrahedra and parallelepipeds, spherical geometry, the regular solids, and the elements of perspective. In conclusion, we have the determination of the surface and volume of a sphere. It will be seen from this mere list how liberally Mr. Taylor has interpreted his editorial function, and how many important theories he has contrived to touch upon; at the same time, the book is anything but "stodgy," and cannot fail to interest and stimulate an intelligent reader. There is a good index, and here and there brief historical notes are given.

It is instructive to observe how Mr. Taylor has dealt with Euclid's text. He explains in the preface that he began by translating the first book; he ended by "giving up all idea of simple translation, and retaining merely the substance of the work, following closely Euclid's sequence of propositions in Books i. and ii., at all events." To see what this means, let us take propositions 1–26

in the first book. Besides alterations of minor importance, proofs other than Euclid's are given for propositions 5, 6, 14, 24, and the first part of 26; and two additional propositions (10 A, 10 B) are introduced for the purpose of proving that all right angles are equal. It may be thought by some critics that it is injudicious to have discarded altogether so many of Euclid's demonstrations; but, in any case, additional evidence is given of the impossibility of returning to the text of the Elements pure and simple. That the idea of doing so should have, apparently, presented itself to the mind of an accomplished geometer like Mr. Taylor, is very remarkable.

The great merits of Mr. Taylor's work are sure to meet with general appreciation. Experience alone can show whether it approaches more nearly than any of its numerous predecessors the ideal of a school text-book. The reasons why one book turns out to be a good one for teaching purposes, and another not, are often difficult to discover; but we should expect the present volume to undergo the ordeal successfully.

So far as we have been able to test it, the book appears to be very accurately printed; some of the figures are not so exactly drawn as they might be, and the lines (except in Book xi.) strike us as being too thin. The occasional use of small letters instead of capitals, to denote points, is also, we think, undesirable. It is so important to preserve young eyes from unnecessary strain, that even minute details of this kind deserve attention. There is, alas! only too much reason to be assured of the editor's sympathy with the spirit of this remark; for, as we learn from an affecting passage in the preface, Mr. Taylor lost his sight while his book was going through the press. To the mathematician, as to his twin-brother, the poet, sight is perhaps the most precious of nature's gifts of sense. Happily in each case the imaginative faculty, which feels the loss of vision so keenly, not seldom supplies its best alleviation; and we sincerely trust that Mr. Taylor is still able to find solace in the pursuit of his favourite science.

In conclusion, we cannot refrain from quoting the extraordinary regulation for the Cambridge Local Examinations, as printed on the fly-leaf of Mr. Taylor's book:—

"Proofs other than Euclid's will be admitted, but Euclid's axioms will be required, and *no proof of any proposition will be accepted which assumes anything not proved in preceding propositions in Euclid.*"

The clause which we have ventured to italicise makes proofs other than Euclid's not only admissible, but necessary; while the retention of the axioms becomes superfluous, except perhaps for sentimental reasons. How the regulation can be complied with is not very clear to the ordinary mind; perhaps a recent "demonstration" of Euclid's fifth postulate (Simson's eleventh axiom) may be the first instalment of a new geometry without assumptions. Or, possibly, the regulation may be intended as an object-lesson, to illustrate the truth of the assertion that Cambridge graduates cannot write plain English, and thus to support the present agitation for imposing some test of composition in the Little-Go?

G. B. M.

RECENT HISTORY OF THE CARBOHYDRATES.

Kurzes Handbuch der Kohlenhydrate. By B. Tollens. Band ii. Pp. xvi + 407. (Breslau: E. Trewendt, 1895.)

THERE is not much apparent analogy between the province of the carbohydrates and the African continent; but viewed as arenas of research, discovery, and appropriation, they present very similar histories. The author of the work before us has accepted the mission of record-keeper in the march of annexation in the first-named and more abstract region, and he must have found his office during the last ten years quite as engrossing as those who provide us with maps of the once dark continent.

The volume is supplementary to that which appeared in 1888 under the same title (Band i.), and deals with events in this extremely interesting field of enterprise, up to last year (May 1895). If it were not for the self-evident fitness of the number 7, we might have pronounced the selection of time for antiquating the earlier volume as somewhat hasteful; but that would have been before acquainting ourselves with the contents of the present vol. ii. Afterwards, we have merely to record our conviction that seven years has become "quite a" period in "chemical time." Of course, this effectual antiquating of vol. i. in no sense lessens its historical value, and it will continue to occupy a not "too top-shelf" in our library of working manuals.

Like its predecessor, the book is substantially a reprint of an article or monograph written for the "Handwörterbuch der Chemie" (Ladenburg). It is necessarily therefore cyclopædic in style, and restricted in its treatment of the subject to the experimental results of investigations, and their immediate bearings upon current developments of chemical theory pure and simple. Seeing that in the compass of 370 pages the author deals with the substance of 1200 original papers, it will be gathered that he has not indulged in much speculative discussion of the problems peculiar to this borderland between chemistry and physiology. He has produced rather a rigid *précis* of positive results, and, backed by his well-deserved reputation for thoroughness and critical exactitude, the book needs no further recommendation to chemical specialists. But the subject appeals to a wider circle of readers, and it may not be out of place to examine the author's work from a somewhat broader point of view.

The lines of classification adopted are, of course, those laid down and developed by Émil Fischer, and expounded by himself in his two monumental dissertations, "Synthesen in der Zuckergruppe" (*Deut. Chem. Ges. Ber.*, 1890, 2114; 1894, 3189). These are dealt with in the earlier sections. The basis of the isomeric relationships of the glucoses and their immediate derivatives is briefly set forth. In respect of constitution, the discussion as between an aldehyde or ethylene oxide formula for the typical glucose is impartially summed up. We may remark on this important point, that there is no suggestion of the probable influence of aqueous solution. The very recent researches of Lobry de Bruyn (*Rec. Trav. Chim.*, 1895, 14, p. 203), showing that mannose, dextrose, and fructose are reciprocally transformed, each into the two

others by the action of sodium hydrate in aqueous solution, are a striking illustration of the mobile equilibrium of the typical CO group, and of the ease with which its migration is determined. That changes of structure take place in aqueous solution is evidenced by the phenomena of rotation, and the influence of hydrolytic agents points to a very direct connection with changes of "ionic" equilibrium. A grouping of these relationships, with a not too positive conclusion as to their significance, would have added a suggestive section.

From constitution the author proceeds to configuration, the section consisting in the main of Fischer's well-known tables. In the next edition these may be accompanied with advantage by the mnemonic symbols recently proposed by Lobry de Bruyn (*Chem. Zeitung*, 1895, No. 75), or by some similar pictorial concession to the limitations of the average memory. In the nomenclature of the group, there is the usual struggle between systematic and trivial terms. There is some ambiguity created in the numerical basis of the terminology, as between the number of C atoms in the molecule of a simple carbohydrate, and the number of such simple units in the condensed molecule of a "polysaccharide." Thus the term "triose" designates a glycerose of the dimensions C_3, and the sugars of dimensions $3C_6$. The author evidently avoids innovations in this direction, and it is not for us to step in where the leaders fear to tread. In the following sections, dealing with the experimental methods of general significance, whereby the relationships of constitution and configuration have been elucidated, the treatment of the subject is of the briefest. The sections which suffer most under the severe discipline of brevity are those devoted to "the formation of the carbohydrates in nature," and to "fermentation." The former is chiefly devoted to the recent work of Brown and Morris, and the latter to Fischer's observations on the relationship of fermentation to configuration. It is evident that much matter of the greatest interest to physiologists is left unnoticed. We can only regard the omission as expressing the author's judgment that this province still refuses to yield to the positive methods of a systematic handbook. From this condensed review of the generalities of the subject, we are taken at once to the description of the individual compounds in systematic order: glucoses, saccharoses, and polysaccharides. It would be gratuitous to say anything in commendation of these sections. They constitute a condensed reproduction in strictly systematic order of the very prolific researches of the last few years, and the labour which they represent on the part of the author will be fully appreciated by specialists. Anything which might be said in depreciation of these sections could only be translated into the common-place that no one can be a general specialist; and in the chemistry of the carbohydrates the specialising process has passed into the second degree, as witness the literature of the sugars, of starch, of cellulose. The consequent difficulty of subordinating the parts of so wide a subject to the main plan has been effectually overcome in the work before us. The remainder of the work is devoted in order to the alcohols, to derivatives of the cyclic hexamethylene, and lastly to the complex groups of acids which stand in relationships of the first or more remote degrees to the carbohydrates.

The work, therefore, satisfactorily exhausts the recent history of the subject in its systematic relations; on the other hand, to those who have the fear that the objectives of the science in this fertile field of research are being rapidly exhausted, we may speak a word of comfort in the reflection *l'appétit croît en mangeant*. It is evident that, although the writer limited himself to the plan of a somewhat "high and dry" dictionary article, and in enlarging his text to confer upon the article the standing of an independent monograph, keeps well within the limits of history, the subject-matter is continually breaking bounds and revealing by implication the remarkable further developments which it promises on every hand. The natural history of the carbon compounds remains to be written. There is abundant evidence in the recent history of the chemistry of the carbohydrates that this new objective of the science is taking positive shape. These compounds constituting in a prominent degree the arena for the primary processes of natural organic synthesis, it is in the order of things that the fundamental relationships of these compounds should be first elucidated as the necessary basis of plant physiology. It would take us much beyond the obvious limits of the matter in hand to attempt a discussion of the many broad physiological issues directly raised by the results of the last seven years' investigations. We would suggest that the author's next volume should treat this side of the subject specially and adequately. We should also suggest an historical preamble and a brief survey of the chief developments marking the period. With these slight qualifications, we heartily commend the book to all students of natural science.

OUR BOOK SHELF.

Practical Inorganic Chemistry. By Dr. G. S. Turpin, M.A. Pp. 158. (London: Macmillan and Co., 1895.)

IT is gratifying to all who are interested in scientific education to know that instruction in elementary science in this country is steadily improving, both in methods of teaching and in the subjects taught. In the spring of this year, a new scheme of work for organised science schools was issued by the Department of Science and Art. These schools include all the best carried on in connection with the Department, and for some time a definite scheme of study, extending over three years, has been followed in them. What the Department did recently was to issue a remodelled scheme for such schools, embodying several commendable features. Elementary practical physics was introduced as an obligatory subject, and a course of real chemistry was substituted for the drill of test-tubing, which had gone under the name of practical chemistry for so long. Dr. Turpin's book has been designed to meet the improved requirements; and, as it has had a reasonable basis for its construction, it possesses many good qualities. The course of work described begins with weighing, measuring, the determination of relative density, and other elementary physical principles; then follows a chapter on mixtures and compounds, and another on the setting-up of apparatus. After this fundamental knowledge has been experimentally studied, the constitution of the air is investigated, and then the most important gases, and common chemical compounds, form the subjects of the student's work for the remainder of the course. We cannot speak too highly

of the introduction of such a course of work as is herein described. It encourages thought, creates interest in chemistry, and furnishes the kind of knowledge most likely to prove of advantage in after years. Not only in organised science schools, but in every school where chemistry is taught, the course described in this book could be profitably introduced.

Observaciones de precision con el Sextante. Por el Conde de Cañete del Pinar, Cápitan de Fragata Retirado. Pp. 180. (Madrid: Ricardo Álvarez, 1895.)

A DESCRIPTION of the sextant and the uses to which it can be applied is here given in seven chapters, of which the first describes the instrument, and shows how it may be corrected. Following, we have four chapters on different means of the determination of latitude by means of stars, showing the methods trigonometrically, and also giving examples. The accuracy of observations taken by the sextant is graphically shown by two tables, giving the latitude obtained on several successive days. Lastly, we have a description of the means by which time is determined, and also how the longitude is obtained by means of the moon and stars. Throughout the book there are numerous examples, and no pains have been spared to make it useful.

First Stage Mechanics. By F. Rosenberg, M.A. Pp. 296. (London: W. B. Clive, 1895.)

THIS book has been made to fit the requirements of the elementary stage of theoretical mechanics of solids, as laid down in the syllabus of the Department of Science and Art. It is the first volume of a new series of Departmental text-books, and it possesses all the characteristics of the literature of the University Correspondence College Press; by which remark we mean that the text is concise, the examples numerous, and the comparative importance of the sections is indicated by the thickness of the type in which they are printed. What more does a student require, who is learning theoretical mechanics for examinational purposes?

The Story of the Solar System. By George F. Chambers, F.R.A.S. Pp. 202. (London: George Newnes, Limited, 1895.)

WE are glad to be able to state that the twenty-eight illustrations in this book are better than those in the companion volume on the "Stars," by the same author. Mr. Chambers has contrived to compress an immense amount of information within a small compass, and his descriptions possess the double quality of simplicity and attractiveness. We do not know of a book in which so much is told about the solar system within such narrow limits.

British Guiana and its Resources. By the author of "Sardinia and its Resources." Pp. 104. (London: George Philip and Son, 1895.)

THE question of frontier between British Guiana and Venezuela is now so much to the front, that a large public will be interested in this description of the history, features, and resources of the region in which the debatable land lies. The book will be found valuable not only on this account, but because it is full of information useful to visitors to British Guiana. Travellers of all tastes and inclinations will find that the country offers many attractions, and is as wide a field for observation and collection as could be desired.

Mammals of Land and Sea. By Mrs. Arthur Bell (N. D'Anvers). Pp. xii + 191. (London: George Philip and Son, 1896.)

ALTHOUGH this volume will assist its readers to know the general characteristics of members of the mammalian family, it possesses no novel features, and the illustrations belong to a past age. Some readers may find the book interesting, but few will pronounce it attractive.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A New Method of Measuring Temperature.

THE recent publication of papers dealing principally with thermometry, by Mr. Griffiths, and by the Kew Standardising Bureau, has suggested to me that the publication of a new thermometric method which I have used for some years may be of use.

Briefly, in this method two thermo-junctions are used; one is placed, protected or not, as circumstances dictate, in the substance of which the temperature is to be measured, the other in the bulb of an air or nitrogen thermometer. This junction is blackened, and may or may not be protected, but should be in the same state as the other. The bulb of the air thermometer may or may not be silvered or platinised. Within the bulb of the air thermometer is placed a coil of platinum wire, in series with this being a carbon resistance and a storage battery. The bulb of the thermometer is protected by a layer of slag-wool, or, if this cannot be obtained, of asbestos; or a sheath of polished metal may be used. In the thermo-electric circuit a low resistance galvanometer is placed. I prefer to use a d'Arsonval.

The *modus operandi* is as follows. The free thermo-junction is placed in the substance whose temperature is to be measured. The galvanometer is immediately deflected. The circuit of the platinum heating coil is then closed, and the carbon resistance screwed down till the galvanometer needle comes back to zero, or until making and breaking the thermo-electric circuit produced no movement of the needle. When this is the case the temperature of the air or nitrogen in the bulb will evidently be the same as that of the substance to be measured, and can be directly read off in any of the usual ways on the thermometer. I prefer myself to use the constant volume method.

It is necessary, of course, that the thermo-junctions be both in the same physical state. This is generally secured with sufficient accuracy by cutting the wire from the middle of a much larger piece which has been well annealed. In connection with other work I have found that two samples of metal, chemically identical but having different rigidities and thermo-electric powers, may always be brought to identical states by heating for a time at white heat in vacuo, first introducing, if necessary, oxygen or hydrogen to decompose any hydride or oxide combined with the metal. I have never found it necessary to do this in making thermo-junctions, but its use is recommended to experimenters who are studying the physical properties of metals.

The advantages of this method are as follows:

(1) No assumption is made in regard to any law of variation of thermo-electric effect with temperature.

(2) No assumption is made with respect to variation of voltage of standard cell in relation to temperature. The error due to the fact that the saturation of the sulphate solution of the standard cell always lags behind the temperature, and that due to the fact that the temperature is never known exactly, are thus done away with.

(3) No assumption in regard to temperature or temperature coefficient of wires is made.

(4) Both junctions being maintained at the same temperature for approximately the same length of time, and under the same conditions, the likelihood of changes in physical state, produced by one wire being annealed more than the other, is reduced to a minimum.

(5) The temperature is read directly by a nitrogen thermometer, and no intermediate standards need be used.

(6) No complicated apparatus is needed, the only instrument used being the galvanometer, and that only as an indicator. The only standard used is the kathetometer for measuring the height of the mercury column.

The only assumption made is that the air in the bulb is at a uniform temperature throughout. This assumption is justified, however, by experiment. In 1890 Mr. A. E. Kennlly and the writer made a number of experiments to determine the temperature coefficient of the electrical resistance of copper wire. In these experiments the wire was wound in two coaxial coils in the bulb of an air thermometer, the idea being that there would

probably be a difference of temperature between the coils, and the mean would be taken. On testing the matter, however, no such difference was found, even up to the highest temperature used, 250° C. If any difference existed it was less than one-tenth of 1° C., as that amount could have been measured. This being the case in a narrow tube where the air circulation was hindered by a number of mica discs (see *Physical Review*, February 1893, for description of apparatus), it is improbable that there is any appreciable difference when there is no hindrance to the air currents except the heating coil of platinum.

I have never used the apparatus for very high temperatures, but see no reason why it should not be so used; and it would apparently present a number of advantages for such work, chief among which is the fact that the temperature would be obtained by direct comparison with an air or nitrogen thermometer, and no assumptions made as to the law of variation of thermo-electric force with temperature.

It can, of course, be made self-recording by placing a recording pressure gauge in place of the mercury column, the observer simply keeping the galvanometer at zero by manipulation of the carbon resistance.

It is obvious that platinum resistance coils can be used instead of the thermo-junctions, the platinum resistance coils forming two arms of a Wheatstone bridge, and the galvanometer placed across them.

A method of measuring the heat conductivity and temperature coefficient of metals devised by me, and at present being used by one of my students, may be of interest. A metal bar, well annealed, polished, and with special precautions taken to preserve homogeneity of physical state, has its ends placed in two mercury baths, A and B. The bar is protected from radiation by concentric polished metal tubes. A is heated electrically, and B cooled by a water tube. In the regular laboratory exercise, I have been in the habit of letting the students use thermometers. But in this case, where accurate results are required, capillary tubes are led off from A and B, filled with mercury, thus forming a thermo-junction. Another thermo-circuit has its junctions placed at the entrance and exit of the cooling water. It would, of course, be possible to measure the thermo-voltage directly by standard cell; but instead of this, in the present method, the two thermo-circuits are balanced against one another, the elements which are immersed in the water being chosen so as to have a much higher thermo-voltage than the copper-mercury couple. It is seen, without much difficulty, that by this means the conductivity of the copper may be measured without knowing more than one temperature, and that only approximately, to a considerable degree of accuracy. As the experiments are not concluded, I am unable to state definitely what the value of the method is, but the indications are that it will prove successful. REGINALD A. FESSENDEN.

Western University of Pennsylvania.

On Crookes' Spectrum of Helium.

IN his investigation on the spectrum of helium,[1] Crookes has examined the spectrum of five different samples of gas, two being developed from cleveite (No. 1 and No. 5), another from uraninite (No. 2), and two from bröggerite (No. 3 and No. 4). Sample No. 5 has been prepared with special care, and is designated "helium purissimum." The five spectra are by no means identical, and it has been concluded that besides helium there are other gases present. E. A. Hill[2] has even gone so far as to infer the existence of at least fifteen new elements from the comparison of these five spectra. Thirty of the seventy-nine wave-lengths measured by Crookes coincide (within the limits of error) with wave-lengths that we have measured in the spectrum of cleveite gas.[3] But the remaining forty-nine lines, many of which are strong, do not coincide with any of ours. As far as we know, it has not been noticed that thirty-three of these forty-nine lines almost certainly belong to argon, among them nearly all the stronger lines. Six more may also be argon lines, but the identification is rather doubtful. Two lines in all probability are mercury lines, which naturally are likely to appear in a vacuum-tube made by means of a mercury pump. One line may be due to carbon. The table on p. 246 contains a list of the forty-nine wave-lengths that do not coincide with wave-lengths that we ascribe to helium, and gives their probable origin. The wave-lengths of argon lines are taken from Kayser (*Chemical News*, August 30, 1895), Eder and Valenta (*Ber. der Wiener Akad.*, October 24, 1895), and from Crookes' own measurements.

3890·5 and 3885·9 are strong lines that have been seen in the spectra of all five samples. Crookes considers them as satellites or components of the strong line between them, the wave-length of which is 3888·785 according to our measurements. But as our photographs show that this line is single, or if not single has a weak component 0·05 lower, which can only be observed with much greater dispersion than Crookes has used, we are inclined to believe that 3890·5 and 3885·9 are spurious lines due to some error of apparatus having made their appearance on account of the enormous energy of 3888·8.

Of the five remaining lines, three are only of intensity 2. The two stronger ones have only appeared in the gas from uraninite, and may possibly belong to a substance hitherto unknown. But it is far from being established.

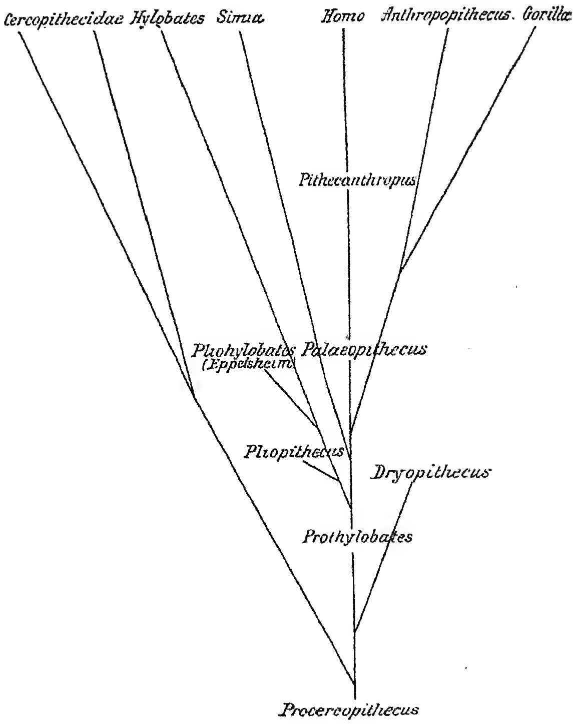
The Place of "Pithecanthropus" in the Genealogical Tree.

IN the report on the scientific meeting of the Royal Dublin Society on November 20, in NATURE of December 5, 1895, it is stated that I placed Pithecanthropus in the genealogical tree, drawn by Prof. Cunningham, below the point of divarication of the Anthropoid apes from the human line. This indeed I did. But this statement could be misleading as to my real views on the genealogy of Pithecanthropus, such as I stated them already on p. 38 of my original memoir ("*Pithecanthropus erectus*, Eine menschenähnliche Uebergangsform aus Java," Batavia, 1894), and more fully at the last meeting of the Anthropological Institute of Great Britain and Ireland, on November 25.



It may not be superfluous to explain my views here by means of the accompanying diagram, representing the evolution of the Old World apes from a hypothetical common ancestor, whom I call Procercopithecus.

In Prof. Cunningham's tree, figured in NATURE of December 5, p. 116, he regards the left branch as all human, the right one as entirely simian, and he placed Pithecanthropus midway between recent Man and the point of divarication.

a There is an argon line at 4933·4 stronger in the blue spectrum seen on our own plates, but not mentioned by Kayser nor by Crookes. Crookes gives 4938 int. 10 as a line of the blue spectrum of argon. But as there is no strong line at 4938, we are inclined to think that it is meant to be 4933. *b* The deviation is too great to suggest the argon line 4879 (Crookes), though its intensity is about the same as that of 4848, and would therefore suit very well. *c* Schuster has also measured these lines, and gives them, together with 4879 and 4726, as characteristic argon lines of the spectrum at atmospheric pressure. *d* H. F. Newall, experimenting with one of our vacuum tubes filled with cleveite gas, found that these five lines appeared in the periphery when it was put into a coil through which the discharge of a Leyden jar passed. We could not detect the lines on photographs taken with an induction current passing through the tube in the ordinary way. *e* Coincidence very uncertain. *f* H. F. Newall gives a line 3918·8 int. 5,* but at this place there is no argon line on our photographs. *g* Coincidence doubtful. *h* Coincidence doubtful. *i* We see a line in the blue spectrum of argon at 3248·4 on our plates. *j* 2536·65 strong mercury line. *k* 2478·66 strong carbon line. *l* 2446·96 mercury line, intensity 6.

* *Astrophysical Journal*, May 1895.

Now I could find no place for the fossil Javanese form, which I consider as intermediate between Man and Anthropoid apes, in any of the branches of *that* tree, only in the third chief line, the main stem, very near to the point of divarication.

Owing to the same circumstances, which indirectly prevented me from explaining my own views on the matter at Dublin, I did not then reply to two remarks of Prof. Cunningham, which omission I now wish to repair by the following declaration.

(1) I did not exaggerate the relative height and quality of the cranial arch, which Prof. Cunningham had in view (the arch of the glabella-inion part of the calvaria) in Hylobates. The profile outline of the skull of *Hylobates agilis* figured, directly from the bisected skull, on p. 8 of my memoir, is even somewhat higher than that of Pithecanthropus, of which I have an accurate bisected cast before me. In the latter the height of the said cranial arch is exactly equal to the one-third part of the glabella-inion line, and in the skull of a *Hylobates agilis* it is about 2 mm. higher than the third part of the corresponding line. If in the mentioned diagram in my memoir that line in the gibbon skull were drawn equal in length to that of the fossil calvaria, instead of the natural size, this would be more apparent there than it is even now. The said cranial arch of a *Hylobates syndactylus* in the same diagram is much lower than that of the other gibbon species, and the same arch in the chimpanzee would even be lower than in *Hylobates syndactylus*. It is easy to find skulls of Semnopithecus with a higher "cranial arch" than the chimpanzee has. Further, between different individuals of the same ape species and of man, we find great differences in the height of that arch.

All these facts tend to show that there is no reason for regarding the height *of the suprainial part* of the calvaria as of real importance in our judgment on the place which any human-like being should occupy in the genealogical tree.

(2) In my original memoir (p. 7), I have already pointed out that the occiput of the fossil skull is very ape-like, especially gibbon-like. But, nevertheless, the inclination of the planum nuchale on the glabella-inion line is very different from that of all the Old World apes. These accord very nearly with one another in the degree of this inclination, whilst the angle in Pithecanthropus approaches closely human conditions. I not only compared photographs of the median line of the skulls, but also the bisected skulls with the bisected exact cast of the fossil calvaria. The means which I have taken to determine the degree of this declination are therefore, I believe, entirely calculated to yield trustworthy results.

EUG. DUBOIS.

An Anagram.

Is it too frivolous to suggest the accompanying anagram?

Pithecanthropus erectus.
Pursue the person, catch it!

Kew, December 10, 1895. E. H.

The Barisal Guns and Similar Sounds.

WITH reference to the letters that have appeared in NATURE on the above subject, I have read with interest that by Mr. G. B. Scott, of the Indian Survey, in your last issue. The question, I think, arises, Are we not dealing, in India at least, with two very different phenomena? Are these sounds like that of heavy ordnance, which are heard occasionally at the base of the Eastern Himalayas and the Garo and Khasi Hill Range,[1] the same as those longer known and more familiar as the "Barisal Guns"? Mr. Scott's description of the sounds he heard when on board the steamer moored in the narrow channels near the sea, are remarkably like wave action. He says: "Sometimes a single report, at others two, three or more in succession, never near, always distant, but not equally distant. Sometimes the reports would resemble cannon from two rather widely separated opposing forces, at others from different directions but apparently always from the southward, that is, seaward." This is precisely what one would hear on a still night, when an ocean swell was coming up the Bay of Bengal and breaking all along a low shore with an undulating outline stretching many miles east and west.[2] I have been twice round by Barisal in a river steamer, and once by native boat, which took many days; but I was not fortunate enough to hear the sounds.

[1] *Vide P. A. S.* Bengal. Mr. La Touche, of the Geological Survey, p. 201, in "Report on Barisal Guns."
[2] *Vide* same Report. Letter by Mr. A. Manson, p. 208.

Regarding the distant booming reports, that are heard further inland, I was, I think, one of the first to notice and put them on record. In the *Proceedings* of the Asiatic Society of Bengal, March 1869, *vide* "Notes from Asaloo, North Cachar, on the Great Earthquake of January 10, 1869," after giving some details of the daily shocks that were recorded up to the 17th of that month, I find the following on p. 98. "Very noteworthy is the distant report of a heavy gun on January 19, heard towards the west at 1h. 49m. 19s. p.m. (I was sitting at work at a table outside the office tent); the time I took immediately by chronometer, as I fully expected a shock to follow. Another very loud explosion was heard from Mahadeo Peak at midnight of the 29th, and again from the same peak at 7 a.m. the next morning, the 30th; but no shock came after, on either occasion.

"I may here mention that last cold weather, on several occasions when I was in the North Cachar Hills, I heard, at various times, the like distant reports, resembling exactly the firing of big guns at a great distance. In one or two places the country people had noticed it, and they even used the expression that it proceeded from the earth (*the earth speaks*).

"These subterranean explosions must be heard over large areas, and it would be interesting if they could be noticed, or rather if those hearing them would make the matter public; I have no doubt there are many individuals who will remember having heard such sounds." The reports like big guns, "top chalta," as the natives expressed the sound, heard at Asaloo in January, during a period of great seismic activity, were, I consider, intimately connected with it; and that the similar reports, solitary instances not continuous, heard in the previous year at different places in the same range, were also of a subterranean nature. Seismic sounds are not always accompanied by a disturbance of the earth conveyed to the senses. I find in my journal the following.

"*Nongtung, in Jaintia Hills, December* 21, 1887."

"While seated at dinner, a curious rumbling sound was heard in the west. Mr. Ogle immediately said, 'that is the rumble of an earthquake,' and we waited with intense expectation for several seconds for the shock, I with my watch out ready to take its duration; but it never came. We then thought it might have been a herd of elephants coming up the ridge, and, disturbed by our camp fires, had rushed off through the jungle; but on going into Jawai on Christmas Day, we learnt that a shock had been felt there on the same date and time, and that it apparently came from the west."

The best-defined unaccountable sound occurred when I was surveying the Bhutan Dooars in the spring of 1865. I have some remembrance of putting it on record at the time, perhaps in my annual report. I was standing at the plane-table in the forest twelve miles south-west of Buxa, when the report of a heavy gun was heard in the direction of the mountains, clear and distinct, yet a long way off, followed closely and at irregular intervals by two other discharges. The natives with me immediately said "the Bhutias have attacked Buxa," which was not unexpected, for they had only lately retaken Dewan Giri. A short time after, on reaching the main path from Buxa to Balla, an irregular cavalryman of the Jat Horse came by, carrying despatches for Buxa Fort. I wrote a hasty note to an officer there to ask what was going on, and I received in due course a reply saying not a shot had been fired there or anywhere else. These reports were louder and more distinctly like artillery fire than any I afterwards heard in the hills further to the east. These last had the nature of a very, very distant boom, coming from no well-defined direction. Particularly do I recall one occasion when we were going down a narrow spur on the southern face of the Jaintia Hills, on a glorious fine day, the view over the basal slopes all clothed in forest, and the plains and low hills of Sylhet beyond fading into the high horizon of the delta of the Brahmaputra. The sound seemed to come from out of the distance along the foot of the mountains—west and south.

As a primary cause, every possible kind of force has been suggested—fireworks, *i.e.* bombs, cannon, bursting bamboos in jungle-fires, thunder-claps, landslips, and the falling of river-banks. I am familiar with the sounds produced by all these causes, and the last-named was particularly brought under my notice when proceeding by boat on the Megua and Brahmaputra, and from Gowhatty on a raft made of two dug-out canoes to Doobri, 125 miles. I have often seen and heard the report which

a large long mass of sand, suddenly giving way and falling forward from the vertical face of a sand-bank or river-bank on to the water, will produce, and the very long distance it will be heard up and down the river.

In the vicinity of such great rivers, at such a spot as Chilmari Ghât, which I know well, we must be rather sceptical with regard to sounds being any other than of this nature. The reports are very likely to be repeated, for the wave produced on the water will set another mass falling some way off, and even the wave of air may do the same to a mass just tottering, and bring it all down together (see also Report in *Proceedings* of Asiatic Society, Bengal, p. 207, regarding the echo from one side of the river to the other, so well described by Mr. Manson).

Mr. W. T. Blanford has suggested to me landslips for the reports heard near Buxa; but this is a sound I have heard on the bursting of a landslip dam in the Himalayas: the sound was of the nature of a rumble, not a report. A fall of rocks into a valley from any height would produce, I think, a still more prolonged rumbling sound—more like that of the avalanche.

Shalford Park, January 7. H. H. GODWIN-AUSTEN.

ALLOW me to mention, for the information of those of your readers who take an interest in this subject—a considerable number, to judge from the correspondence that has lately appeared in these columns—that a very complete account of the phenomenon is now being published in *Ciel et Terre*, a review devoted to astronomy, meteorology, and terrestrial physics, published twice monthly at Brussels, from the pen of M. Ernest Van den Broeck, curator of the Royal Museum of Natural History of Belgium, who has devoted much time and labour to a study of the subject. The first article, containing a complete historical review of the subject, appeared on December 1; the second, on the 16th, dealt with the accounts of the phenomenon received by M. Van den Broeck from various observers in Belgium; and future articles will be devoted to a study of the facts as reported from Bengal, to the causes of the phenomenon, and to the methods employed in determining its origin.

I may mention that the true rendering of the word *mist-poeffers*, the name given to the sounds by the fishermen, is not *fog-dissipators*, but, as appears from a note on the etymology of the word by one of M. Van den Broeck's correspondents, it should more correctly be translated *fog-belchings* or *fog-hiccups*, the French rendering of the word *poeff* being *renvoi* or *hoquet*. The point is of some importance, since the sounds do not appear to have any effect, as one might imagine from the signification of the name, as it first appeared in NATURE, in the dispersal of fogs. T. D. LA TOUCHE.

Boring a Coral Reef.

WILL you be good enough to allow me to correct a somewhat important oversight in the note in last week's NATURE, on the work of the Coral Reef Committee of the Royal Society. You mention that the Royal Society has granted the sum of £800, and the Government a gunboat, for the expedition. Even with this help, however, it would have been impossible to undertake the work unless the Department of Mines of the New South Wales Government, largely through the good offices of Prof. Anderson Stuart, had granted to the Committee the use of a complete set of boring tools and appliances, with an engine and boiler. Further, the Department has relaxed the somewhat stringent restrictions usually placed on the use of the tools, owing to the difficulties which will be experienced in a waterless and sparsely inhabited island. For such generous assistance, and to Prof. Stuart, who has helped in many different ways, the Committee cannot be too grateful. W. W. WATTS,

(Joint-Secretary of the Royal Society's Coral Committee).

Sutton, Surrey, January 11.

Variability of Red Stars.

ACCORDING to a notice, which I found in NATURE'S "Astronomical Column" of November 14, 1895, my theory of the variability of red stars should demand, that the bright lines of hydrogen should be produced there at a low temperature and in a condition never tested by experiments.

I will try to show that this objection is not valid.

The bright lines in red stars are considered by me as caused by the recently much studied phenomenon of luminescence, *i.e.* by a production of light not due to elevation of temperature, and thence not subjected to Kirchhoff's law of absorption.

In the cooled atmospheres of the red stars two causes of luminescence can be expected—two causes, which according to the relatively low temperature of the combinable elements and condensable vapours, with which these atmospheres are filled up, must act there much more energetically than in other stars. These two well-studied causes of luminescence are chemical action and electricity.

If we first consider chemical action, it may be stated, by the way, that the supposed chemical combination in a cooling star does not necessarily require a very low temperature. Acetylene, for instance, can be generated in the electric arc. Now we know that acetylene is a compound actually present in the atmospheres of some of the most cooled stars. It is abundantly absorbing in the stars III *b* and, according to Prof. Lockyer, not unlikely radiating in the stars of his Group II. (Vogel's Class III *a*).

If therefore we assume that it is principally acetylene, which is generated in the cooling atmospheres of the red stars, bright lines of hydrogen may be expected there. These lines are then precisely caused as those of sodium, potassium, lithium and thallium in the experiments of Pringsheim, being absent as long as the sodium vapour is only strongly heated, but appearing immediately as soon as in this heated vapour some chemical change occurs.

It must be conceded, however, that in the case of hydrogen this chemical luminescence has not yet been actually observed in our laboratories. But in the case of hydrogen we have another luminescence, which is daily experienced. It is the glow in Geissler tubes, where (whatever may be the heat of the individual shining molecules) the average temperature of the glowing gas does not necessarily exceed the common temperature of our atmosphere, and cannot therefore be considered as the cause of the glowing of the gas.

As this luminescence is caused by electric discharges, and as such discharges (according to what we know about the electrical phenomena connected with the formation of clouds and hail in our own atmosphere) are likely to be expected in atmospheres, which are filled up with vapourous matter ready to condense in clouds, the hypothesis of an electrical luminescence of the hydrogen in the atmospheres of red stars seems very plausible. That hypothesis demands that the bright lines should be especially conspicuous in stellar atmospheres, where the alternation of vapourisation and recondensation is also very conspicuous, *i.e.* (according to my theory explained in the November and December numbers of *Knowledge*) in the atmospheres of red variables and Novæ, where that intermitting condensation and vapourisation of dark obscuring cloudy matter is the very cause of the variability. Now we know that this demand is fully verified. Prof E. C. Pickering has stated as a rule that, with perhaps a single exception, every red star with bright hydrogen lines is *eo ipso* variable. And this rule has proved to be so sure, that Mrs. Fleming could discover numerous new variables from the bright lines of their spectra (*Astrophys. Journal*, I. p. 27, 411; II. p. 198).

Eventual bright lines in the stars of Vogel's Class I. and II. may be explained perhaps (as Prof. Scheiner has recently shown in his "Untersuchungen über Spectra der Helleren Sterne," p. 223) by the hypothetical presence of a gigantic incandescent atmosphere, whose radiation around the bundle of rays coming to us from the star's much smaller photosphere is greater than the absorption it causes in that bundle; but in the more cooled atmospheres of red stars the chemical compounds there present, attest a temperature relatively so low that we cannot conceive that atmospheres to be filled up to such a gigantic height with hydrogen so enormously heated as to become (if that still doubtful phenomenon is possible) bright shining by incandescence.

Such enormously heated hydrogen and chemical compounds cannot permanently coexist in a stellar atmosphere. The coexistence of chemical compounds and bright shining hydrogen is only possible if the brightness of the latter is due to luminescence.

The ideas here suggested may be considered as an instance of a likely fruitful application of the study of luminescence to stellar spectroscopy. If they are right, they give, I think, a plausible explanation (1) of the connection between the variability of a star and the frequent brightness of its spectral lines, and (2) of the very remarkable fact that both variability and bright lines are so often observed precisely in those stars, whose

atmospheres, according to the chemical compounds or their spectra, are coolest. A. BRESTER.

Delft (Holland), November 30, 1895.

THE above amplification of Dr. Brester's views, as to the cause of variability in red stars, calls for a few remarks. Although opinions may differ as to the constitution of stars of Group II., it is generally agreed that those of Group VI. are in an advanced state of condensation, with cool, absorbing atmospheres, and it is in the latter group of stars that we find the full development of the fluted absorption spectrum which Dr. Brester ascribes to acetylene. Experimental evidence does not certainly indicate that this gas is responsible for the dark flutings observed, for other compounds of carbon give a similar spectrum; but, to whatever the flutings may owe their origin, they are a result of Kirchhoff's law. Notwithstanding that it is in these stars of Group VI. we should most expect the bright lines on Dr. Brester's theory, no bright lines have been recorded in variable stars belonging to the group; that is, there is no visible chemical luminescence.

It is in the variables of Group II. that the bright line phenomena occur, but the associated dark flutings of metals, or their compounds, do not lead us to suppose that the temperature is lower than in the other group of stars with fluted spectra. Hence, luminescence does not seem to be more probable in Group II. than in Group VI., unless we accept the view put forward by Mr. Lockyer, that the physical constitutions of the two groups of stars are essentially different. If the stars of Group II. consist of uncondensed swarms of meteorites, it is certainly conceivable that the luminosity of the hydrogen in the interspaces may be partly due to electrical excitation; this view involves the supposition that these stars are becoming hotter.

It may be further remarked that there is abundant experimental evidence to show that the line spectrum of hydrogen can coexist with a fluted spectrum. Acetylene, for instance, exhibits such a mixture, and hence luminescence is not more necessary to explain the luminous phenomena in the case of hydrogen than in the case of the absorbing vapours which give the flutings associated with them in stars.

THE WRITER OF THE NOTE.

Mount Wosho.

As my name has been mentioned in NATURE for December 5, 1895 (p. 107), in connection with recent explorations in Africa, allow me to say that snow clothing on Mount Wosho must have been added by an outsider, for in page 110 of my work on Ethiopian geography, published five years ago, I have expressly said that snow does not exist in that country. In page 387 of the same volume, I have given up all Mount Wosho's claims to an immense height; but I still think it exists as a mountain, and that it ought not therefore to be wiped off the map.

Your criticism induces me to explain how I tried to sketch one in Upper Ethopia. I first employed the common method by recording hours of travel and bearings by compass; but I was then forced to suppose the variation of the needle. Disturbing attractions could not be eliminated, and it was seldom possible to check my road by observed latitudes. However, as a warning to my successors, I published this tedious work in my "Géodésie d'Ethiopie" (Paris, 1873), a volume of 502 quarto pages.

This first attempt to map the country being fruitless, I turned all my attention to using a theodolite, and collected in 318 stations more than 4000 bearings, besides 500 of the sun, taken at proper hours to get true azimuths, each of these being followed by an angular zenith distance. I obtained three base-lines from differences of latitudes observed on two heights situated near the same meridian and connected by azimuths. The northern base is nearly 51 miles long; I got there my longitude by eight occultations of stars. The second base is 52 miles calculated from a quadrangle, and the southern base, still more indirect, reaches 51 miles. I have thus carried a continuous chain of triangles from the Red Sea to the frontier of Kaffa, a distance slightly greater than from Calais to Bayonne. These triangles, mostly with only two observed angles, have been checked here and there by latitudes and independent longitudes. I got the latter by a few occultations, but chiefly according to the Russian method of lunar observations. By this method I have calculated 857 positions in Ethiopia. They are given in my pages 423-440, the heights being obtained by a *supposed* coefficient for terrestrial refraction.

In my "Géodésie" (page 195) I give the first mention of Mount Wosho as *probably* Wosho, and the following page says, "flat mountain which I suppose (*que je prends pour*) Wosho." Page 438 points in No. 805 to a note (p. 448) which adds, "placé pur renseignements et par ces azimuts réitérés." This hearsay evidence is taken from a list of days' journeys between Bonga and Wosho (published in my "Géographie") without details. The profile of the mountain measured from Falle is given in the collection of sketches belonging to my 325 *tours d'horizon*. Moreover, the zenith distance was 90° 21′, nearly the very worst to be corrected by the ordinary rule for terrestrial refraction. In spite of all these drawbacks, I published the resulting enormous height in order to call attention to Wosho. Let us hope that some explorer, after throwing a net of triangles over Walamo, may put in its proper place and height the real Wosho.

ANTOINE D'ABBADIE.

Hendaye, December 13, 1895.—

I AM aware that M. d'Abbadie did not still maintain the exaggerated importance once attached to Mount Wosho, for which, indeed, he is by no means solely responsible. My remark was suggested by the fact that the great mountain reported by Grixoni's expedition had again called attention to Mount Wosho, and led to the idea that the earlier reports were possibly, after all, correct. But until Dr. Donaldson Smith's maps are published, it is no use attempting to reconcile the previous maps of this region. THE WRITER OF THE NOTE.

Cactaceæ in the Galapagos.

ALTHOUGH the Editor has kindly replied to that part of Mr. Agassiz's letter [*ante* p. 199] relating to the *Albatross* Expedition, I should like to say a few words on the other points raised by him. In the first place, I regret that my communication on the subject should have produced the impression of unfairness towards any person or persons. Such was not my intention. For the sake of my own reputation, as well as for the information of those who, like Mr. Agassiz, might, from my way of expressing myself, think otherwise, I may add that I did not intend to convey the idea that *Opuntia* and *Cereus* are limited to Chili on the west coast of America. The contrary is so well known, that it did not appear necessary to me to enter into particulars. Of course Mr. Agassiz will hold me guiltless of suppressing anything respecting the branches of *Opuntia* and *Cereus* which he says he collected, though he does not know what became of them.

Perhaps I may also be permitted to add that Dr. Baur has since sent me some very fine photographs of *Opuntia* and *Cereus*, on a comparatively large scale, together with some notes, which I laid before a recent meeting of the Linnean Society.

Herbarium, Kew. W. BOTTING HEMSLEY.

A Luminous Centipede.

IN Mr. Lloyd Bozward's letter on the above subject in this week's NATURE, he says that the light of the *Scolopendra electrica* "is the same as that of the glow-worm." My experience is that the light of the glow-worm is a clear little *spark* of light; whereas that of the *Scolopendra electrica* (which I have usually found in the autumn) is more of a phosphorescent light, and streaks of this light are left for a few seconds in the trail of the animal as it crawls about, so that it is often difficult to say exactly where the creature is. I have no doubt others have observed the same thing. T. PLOWMAN.

Enfield, N., January 11.

The Critical Temperature of Hydrogen.

WHAT I object to is not Mr. Bryan's reference to Wroblewski's work, but his statement (explicitly founded upon the absence of "fresh experiments") that my conclusions "are not results of independent original investigation." In his letter to NATURE of January 9, Mr. Bryan does not even attempt to justify this statement. My *Bulletin* paper was an abstract; in the full paper (*Trans. Crac. Acad.*, vol. xxvii. p. 375), published May 1895, Wroblewski's work was quoted and discussed.

Cracow University, January 12. L. NATANSON.

A Fog Scale.

CONSIDERING the important part that fog plays in determining the character of a health resort, it is remarkable that no

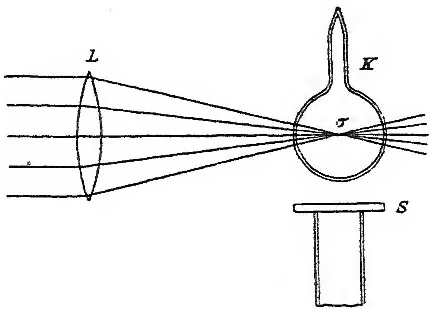
scale similar to those adopted for wind and cloud should have been hitherto used in meteorological reports. Like the above scales, it could only be approximative; but if observers fixed upon conspicuous objects, such as hills, churches, &c., at known distances for their observations, these ought to be at least as accurate as those for wind and cloud.

Nant-y-Glyn, Colwyn Bay. ALFRED O. WALKER.

FLUORESCENCE OF SODIUM AND POTASSIUM VAPOURS, AND THE IMPORTANCE OF THESE FACTS IN ASTROPHYSICS.[1]

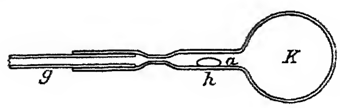
IN the case of unmixed vapours, E. v. Lommel (*Wied. Ann.*, p. 856, 1883) has proved a fluorescence for iodine vapour, and this has been shown also by us (*Wied. Ann.* 56, p. 18, 1895) to be true for the vapours of numerous organic substances. In our latest experiments we have studied the behaviour of the vapour of metals in this respect.

(1) *Order of Procedure.*—For the experiments the following arrangement was adopted. Rays of sunlight were made to fall on a double convex lens, L, of focal length 5 cm., which brought them to a focus at a point, σ, in the centre of a glass spherical bulb, K, filled with vapour.



To one side of the bulb was placed a spectroscope with the slit horizontal, the edge of the prism also being horizontal. The spectroscope was fixed by its legs on a board placed vertically, and could be revolved round its axis by means of a movable cone on the inside part of one of the feet. One was able also to adjust the collimating telescope on the cone of fluorescence proceeding from the inside of the bulb.

The bulbs, which were made principally of hard glass, were filled with sodium, potassium, and other metals in the following manner.



In the first place, a small quantity of the metal was placed in the bulb K, the neck then drawn out, and at its extremity connected with a tube of soft glass, leading to a mercury pump. The metal was then placed in position *a*, and warmed during continuous gentle pumping, in order to get rid of all water vapour and CO_2; each bulb was also several times cleaned out with hydrogen. The heating was then increased, and when a convenient quantity of the metal was distilled the tube was sealed off by means of the blowpipe. In most cases the diameter of the bulb was 5 cm., so that it could be easily enveloped in a flame. We have also employed bulbs made of soft glass and of various sizes, but the optical effects were exactly the same. Difficulties were met with when employing the alkali metals; for, as soon as the vapour began to be formed, the bulbs became browned and blackened, so that new ones had to be substituted.

(2) *Results.*—The experiments showed that the fluorescence of sodium and potassium vapour was bright—the former green, the latter intense red.

The fluorescence can also be beautifully seen by observing the vapours of these metals in the light of an arc lamp. In cases of the less volatile metals, we have not yet been able with perfect confidence to prove its presence, although the vapour of cadmium undoubtedly at the surface of the melting metal displayed a green fluorescence colour. The failure, however, of these experiments may be explained partly by the poor intensity of the rays of the winter sun. We shall, naturally, repeat them in summer.

The fluorescence spectrum of sodium vapour was made up as follows:

675.	Boundary of the red.
675—602·5.	Bright red band.
602·5—540.	Dark band.
540—496.	Green fluted band, composed of single dark and bright lines.

In the blue there is practically nothing visible.

At the less refrangible end of the dark band 602—540, the yellow sodium line appeared.

The appearance of the bright line of sodium was not caused by the presence of the flame used for heating, because when this was removed, the line remained still bright; nor could its presence be explained by the action of chemical processes taking place in the bulb, because the moment the incident light was cut off it disappeared.

The fluorescence spectrum of the vapour of sodium[1] is made up of three parts: (1) the non-fluted band in the red, (2) the fluted band in the green, (3) the bright sodium line in the yellow.

Whilst in the cases of solids and liquids which exhibit fluorescence the fluorescence spectra consist of broad ill-defined, continuous streaks, we meet here also fluted bands, as shown by other gases under the action of electrical discharges, and single lines.

The fluorescence spectrum of potassium displays at 695—615 an intensely red band.

Adjoining this band the dark interspace is relieved by the somewhat brighter appearance of the green, due, perhaps, to the presence of some sodium vapour.

The bright lines of potassium could not be proved, but their absence may be accounted for by the feeble intensity of the incident light.

The fluorescence spectrum of lithium could not be observed, because so soon as the lithium was placed in the bulb and heated, the glass exposed to the light-source became affected. By further heating, the vapour given off displayed only the green fluorescence light of sodium. For the same reason experiments to obtain in discharging tubes, the "elekroluminescenz" of lithium were unsuccessful.

(3) *Validity of Stokes' Law for the Fluorescence Light of Metallic Vapours.*—We have also made investigations to find out whether here the law of Stokes—that is, whether the *excited* rays of light are less refrangible than those *exciting*—holds good. To this end a spectrum was formed by means of a prism, but only a small strip of this was employed, and led by means of a lens into the bulb filled with vapour. In the case of the vapour of sodium the intense green light radiated was excited, in

[1] Translation of a communication to the "Sitzungsberichten der physikal. med. Societät zu Erlangen." By Eilh Wiedemann and G. C. Schmidt.

[1] A comparison of these fluorescence spectra with that which is obtained by the heating of sodium vapour exhibits certain relations (Evershed, *Phil. Mag.* (5), 39, p. 460, 1895); the same is the case with both sodium and potassium, if the positions of the fluorescence spectra be compared with the absorption-band-spectra investigated by H. E. Roscoe and A. Schuster (*Proc. Roy. Soc.* London, 22, 262, 1894). In both cases the radiation towards the red appears altered.

the first place, by the green-blue rays; and the red by the yellow and red rays. Potassium, when excited by red light, emitted light of a deep red colour.

These experiments show that at least no very marked deviations from Stokes' law exist.

(4) *Applications to Astrophysics.*—We wish to point out in a few words the importance, for astrophysical problems, of the preceding observations concerning the fluorescence of the metallic vapours.

We know that in the atmosphere of the sun there exist vapours of different metals which are radiated from the sun; these must also exhibit fluorescence, and that of a bright nature. We must also remember that the intensity of the exciting light in the region of the sun is much greater than that near the earth's surface, and also the same may be said of that of the fluorescent light. These rays of fluorescence do not follow Kirchhoff's law.

The radiated fluorescent light is made up of coninuous and fluted bands and single lines. By mixing several metals together the continuous bands grouped themselves and formed a continuous spectrum, the delicate, and sometimes less recognisable, fluted bands, however, of several substances neutralised each other, and so became invisible. Each of the sharp lines, on the other hand, remained visible. We have thus, for example, a very simple means of explaining the spectrum of the corona, which consists of a continuous spectrum and single bright lines. It is then unnecessary to assume that luminosity is produced by a continuous agitation depending on electrical oscillations; agitations which, nevertheless, play in many cases an important part. Applications of these results may also be found to be closely related to the theory of the chromosphere, certain forms of prominences, &c.

In all astrophysical and other light phenomena (*Strahlungserscheinungen*) special discussions will be necessary, not only from the point of view as to which portions of the ray are the result alone of an increase in temperature, and which depend on "luminiscence" (*luminescenz*), but it must be especially made clear when we have before us "photo-luminescence" and when "fluorescence." In this case the conditions are relatively simple, and for experiment easily accessible.

(5) *General Remarks.*—The case of the fluorescence of rarefied vapours of potassium and sodium as investigated by us, might be the simplest possible when once the light-producing molecules of the vapourous body under investigation are almost uninfluenced by the action of its neighbours, if we disregard the short spaces of time during which two or more molecules occupy in their respective reactions. Then they behave just like the molecules in bodies of a solid and liquid nature.

Further, the vapours of sodium and potassium consist of single atoms (*einatomig*), so far at least as can be judged from vapour densities established up to the present. The fact, that in these vapours not only band- but also line-spectra make their appearance, necessitates, for the theoretical investigation of fluorescence, the adoption of a new point of departure, more especially if the fundamental movements of the molecules among themselves in fluorescence be investigated.

(6) *Result.*—The fluorescence of sodium and potassium vapours is bright; the former green, the latter red. In the fluorescence spectrum of sodium vapour continuous and fluted bands appear, in addition to the bright sodium line.

Stokes' law is probably valid for the fluorescence of the vapours of metals. The fluorescence of the vapours of metals gives a means of explaining a series of astrophysical phenomena.

(Experiments with helium and argon are in process of investigation.)

NOTES.

M. CHATIN has been elected the new Vice-President of the Paris Academy of Sciences, in the place of M. Cornu, who has passed on to the presidency.

THE French Government has paid a graceful compliment to Prof. Virchow, by nominating him Commander of the Legion of Honour.

THE United States Congress has already made a good beginning as to matters scientific and educational. One of the first subjects to which attention was called, after the opening of the current session, was the proposed joint meeting of the three associations of English-speaking people for the advancement of science, at San Francisco in 1897, namely the Australasian, American and British, following the Toronto meeting of the British Association. A Congressman from Brooklyn presented a memorial and petition from one of the original Fellows of the American Association, setting forth the plan for such a meeting of these associations, and requesting aid from Congress to put the American Association on equal footing with the British in regard to transportation of members across the continent, which it is supposed that the Canadian Pacific Railway will furnish nearly or quite free to the latter. The same member a few days later introduced a resolution in favour of the metric system. Should the three science associations succeed in holding a joint meeting, this subject would well deserve careful consideration.

TWO appeals for funds to fit out Polar expeditions have lately been made—one for support of Captain Jackson's scheme for the exploration of the North-East passage, the other for means to equip a British Antarctic expedition. Captain Jackson proposes to determine whether the North-East passage from Europe to China and America is really practicable to merchant vessels properly fitted for the Northern Seas, and to make as many scientific observations as the equipment of his expedition will allow. If he cannot obtain funds to purchase and equip a suitable ship, he announces his intention to proceed to Polar regions in his yacht *Venture*, a boat only thirty-seven feet long. The Honorary Secretary of the Committee that appeals for support on behalf of Captain Jackson's scheme is Mr. E. R. Suffling, Blomfield Lodge, Portsdown Road, London, W.

THE Executive Committee for the British Antarctic Committee hope to obtain £5000 to be expended on outfits and supplies for twelve scientific men to spend a year in South Victoria Land. It is proposed that these investigators shall be conveyed to Cape Adair by a commercial expedition now being formed with the object of operating near Victoria Land. The party is expected to leave on September 1 next. After calling at Melbourne they will sail direct to Cape Adair, which, under favourable circumstances, should be reached in about fourteen days. There they will be landed with their outfit and instruments, and remain for one year, after which period they will be called for and brought back by the commercial party. The following is a general plan of the proposed investigations to be carried on at Victoria Land by the scientific members of the expedition: (1) A land party will work towards the South Magnetic Pole, there to make magnetical observations. (2) The coast-line of the open bay will be surveyed, fjords and bays explored and sounded. (3) Zoological, botanical, mineralogical and geological collections will be made. (4) Dredging. (5) Barometrical, thermometrical, meteorological and pendulum observations. (6) Air and water current observations. If this programme is only carried out in part, valuable additions to scientific knowledge will undoubtedly be obtained. There are many who are eager to labour in the

unexplored fields of the Antarctic, and already a considerable proportion of the sum required to enable them to do so has been promised. All who are interested in the advancement of Antarctic researches are invited to send subscriptions to the Chairman of the Executive Committee, Royal London Yacht Club, 2 Savile Row, London, W.

MEMBERS of the engineering profession, who believe in the progress of industries through science, will be interested to learn that, according to *Science*, a movement is in progress, in the United States, having for its object the development of a system of mechanical engineering "experiment stations," on much the same basis as the existing agricultural experiment stations. It is anticipated that the outcome will be the organisation of such stations in all the agricultural and mechanical colleges of the country in which the agricultural experiment stations have been successfully organised and operated. The purpose of the movement is to secure the promotion of engineering research, and of the development of the scientific facts and principles which are of most value to the mechanical arts and to the profession of engineering. The headquarters of the central office, to which all will report, is thought likely to be the Bureau of Steam Engineering of the Navy Department; that being the largest, most important, and most generally suitable of the Government Bureaux to take cognisance of such work as is contemplated. A Department of Mechanical Arts was proposed years ago, probably earlier than the Department of Agriculture; but the importance of the former has not been as promptly or as fully recognised as that of the latter, and nothing has yet been done in that direction. Should such a department be founded, it will naturally become the centre of the work of mechanical engineering experiment stations.

A BILL "to establish the University of the United States," was recently introduced simultaneously in the United States Senate and House of Representatives. It provides for the representation at all times of twelve other institutions of the United States in the educational control of the National University. A National University Committee of one hundred has been formed, embracing the Chief Justices of the United States, ten ex-United States senators, certain ex-United States ministers and governors especially interested, the presidents of a number of colleges and universities, the State superintendents of thirty-seven of the States, and the heads of leading national organisations, scientific and patriotic, together with the chiefs of the Government bureaus at Washington. The measure provides for that higher instruction only which follows the work of graduate institutions, and for the induction of students of post-graduate rank into the many fields of original work in research and investigation. The business affairs are to be managed by a board of sixteen regents, with the President of the United States at its head, six members being such *ex officio*, and the remaining nine to be appointed by the President with the consent of the Senate. The educational officers are to be managed by a university council, composed of the regents, acting jointly with twelve eminent educationists representing as many leading institutions of as many States, holding office, like the Regents, for six years, and appointed on the principle that each of the States may in time have representation. The University is authorised to establish such co-operative relations with other institutions as shall be deemed advantageous to the public interests. Neither partisan nor sectarian preferences are to be allowed in any form. Admission is to depend on competency only. The Bill provides for only a few thousand dollars in each of the years 1897 and 1898, to enable the regents to organise, and for the necessary preliminary work.

IT is stated that the New York Pasteur Institute has purchased a farm of about two hundred acres near Tuxedo Park, to be used as an experiment station.

THE storm that visited New York on December 26–27 was attended by the most violent wind ever recorded there. A wind velocity of eighty miles an hour was noted.

MR. JOHN DONNELL SMITH is again in Nicaragua in pursuance of his botanical explorations, which have already been so fertile in additions to the Central American flora.

WE regret to notice the deaths of Prof. Teichmann, formerly Professor of Anatomy and Physiology at Cracow; and of Mr. Hugh Miller, Geologist on the Geological Survey of Scotland, and author of several geological memoirs.

THE vacancy in the Curatorship of the South African Museum, Capetown, caused by the retirement of Mr. Roland Trimen, F.R.S., has been filled by the appointment to that office of Mr. William L. Sclater, Assistant Master of Eton College, and Curator of Eton College Museum. Previously to his present appointment at Eton, Mr. Sclater was for several years Deputy Superintendent of the Indian Museum, Calcutta.

M. R. SCHLECHTER is intending shortly to start on a two years botanical exploration of the South and East of Africa. His programme includes a prolonged stay in Namaland, the Transvaal, Coud-Bockeveld, Limpopo, and Matabeleland as far as the Zambesi. Subscriptions for his collections will be received by Prof. Schumann, Botanical Museum, Grünewaldstrasse, Berlin. They will be at the rate of 35 marks the hundred.

MR. GEORGE W. VANDERBILT is establishing, on his estate at Biltmore, in North Carolina, a scientific collection of dried plants in connection with an arboretum and scientifically managed forest. As a nucleus he has recently purchased, as we learn from the *Botanical Gazette*, Dr. Chapman's herbarium of Southern American plants, which formed the foundation for his "Flora of the Southern States."

THE Fishery Board for Scotland has been reconstituted in accordance with the Sea Fisheries Regulation (Scotland) Act of last Session. Mr. A. Sutherland is reappointed chairman, Mr. R. W. Cochran Patrick is appointed deputy-chairman, Mr. Donald Crawford legal member, and Dr. John Murray scientific member. The other members are Mr. J. R. Welch, Dr. W. R. Duguid, and Mr. A. Jameson.

A REUTER telegram from Stockholm states that, at the instance of the Ministry for Foreign Affairs, notice has been sent to the Governments of Russia, Denmark, Great Britain, and the United States, of S. A. Andrée's projected balloon voyage to the North Pole, and co-operation asked for on behalf of the expedition. Furthermore, the authorities in the countries surrounding the Polar circle will be invited to distribute some thousands of leaflets, containing illustrations of the balloon, and asking for information as to the time at which the balloon is seen, and the direction of the wind at the moment.

ACCORDING to a Reuter telegram from Teheran, there have been two severe earthquakes in Khalkhal, north of Miana. The first occurred during the night of January 2. It was not felt outside the district, but completely destroyed the large village of Zanjabad and partially destroyed several other villages. Three hundred persons lost their lives. The second shock occurred early on the morning of the 5th inst., and was very severe, being felt more than a hundred miles away. The small town

of Goi was completely destroyed, 1000 houses being laid in ruins, while great damage was done to many villages. The loss of life in Goi alone amounted to 800 persons. A sharp earthquake disturbance was also felt at Meshad and Kelat at 10.50 on the morning of January 8.

DURING last week an anti-cyclone lay over the British Islands, during which the barometer read higher than had probably been recorded before in this country. The *Daily Weather Report* issued by the Meteorological Office on the 9th inst. showed a barometer reading of 31·09 inches at Ardrossan, in the West of Scotland, and the readings over the whole of the northern and north-western parts of the kingdom reached or exceeded 31 inches. The nearest reading to this occurred in January 1820, again on the 9th, when the barometer in Scotland rose to 31·06 inches; which until now had been considered to be the highest on record in the British Islands. In January 1882, a reading of 30·99 inches was recorded in the South of England.

WE owe the following news to Mr. R. H. Scott, who received it from Caherciveen. "On Monday night, January 6, at about half-past seven o'clock, a large meteor fell from the sky and approached the earth from a north-east direction. As it approached near the earth with accelerated velocity, brilliant sparks or particles were shot out from it in all directions. The whole country was brilliantly illuminated for about ten seconds, that is, during the time occupied by the meteor in its descent. When the meteor was apparently within about two hundred yards of the earth, it burst or exploded, and the increased illumination was most remarkable. It was impossible for a person to estimate, even approximately, the place or neighbourhood where this meteor fell. Different persons, viewing it from various standpoints, give different locations, but they all agree that the descent was westward or seaward of this locality. The meteor was, apparently, of a globular form, with a tail about eight times as long as the diameter of the globular portion. All was of the same brilliant radiance, but a few seconds before the end of the fall, or when the meteor was extinguished, the half of the tail furthest away from the body became black."

THE Swiss National Exhibition begins at Geneva on May 1 and terminates October 15. Mr. Theodore Turrettini, Mayor of Geneva, is president of the exhibition, and it is expected that the electrical exhibit will be remarkably good. Mr. Turrettini has recently completed great engineering works near Geneva, whereby the river Rhone supplies 12,000-horse power, to be electrically transmitted six miles to the grounds. This power makes it possible for elaborate electrical works to be shown. There will be a travelling footpath, operated by electricity, traversing the great machinery hall; horseless cabs driven by electricity, appliances for aerial navigation, a multiplying valve-pump, processes for making paper and fabrics, tests of strength on metals, and many other appliances. Prof. Pictet will exhibit his apparatus for producing intense cold, and will demonstrate the uses of very low temperatures. Numerous other exhibits of scientific interest will be shown.

PROF. W. C. RÖNTGEN, Professor of Physics in Würzburg University, is reported to have discovered that a number of substances which are opaque to visible rays of light, are transparent to certain waves capable of affecting a photographic plate. It is alleged that he has been able to utilise his discovery to photograph metals enclosed in wooden or woollen coverings, and has succeeded in obtaining pictures showing only the bones of living persons; the explanation being that, while wood and flesh freely allow the newly-discovered actinic rays to pass through them, bones and metals are opaque to them. So far as we can gather from the reports, Prof. Röntgen uses as his source of light one of Mr. Crookes' high-vacuum tubes, electrically excited. If this is placed on one side of a box containing a metallic body, or if a hand is held in front of it, and a sensitive plate is arranged on the opposite side, a photograph of the metal, or of the bones of the hand, as the case may be, is obtained. The scientific world will look forward with interest to the publication of the details of Prof. Röntgen's work.

THE old question as to the influence of public libraries in disseminating infection is commented upon by the *British Medical Journal*, in the current issue. It is pointed out that an article in the last number of the *Annales de l'Institut Pasteur*, by Du Cazal and Catrin, is devoted to this question, and it is shown that the leaves of book soiled by streptococcus pus, pneumonic pus, and expectoration, or by diphtherial false membranes, were capable after several days of transmitting these maladies to animals inoculated by bouillon in which pieces of the leaves 1 centimetre square had been soaked. In regard to the question how far it is possible to disinfect books that have become charged with a contagium, these authors show that there are considerable difficulties in the way. Of chemical disinfectants they recommend the vapour of formic aldehyde in which calcium chloride has been dissolved. By means of this they obtained complete disinfection, except in regard to typhoid fever. By exposure to high-pressure steam, however, they got good results—the disinfection was perfect and complete. But in the case of bound books the steam had very destructive effects, the millboard being softened and the cloth wrinkled. Stitched books, however, were uninjured, no harm being done either to the paper, the ink, or even to coloured engravings.

IT speaks well for the extension of interest in science that steamships are advertised to proceed from London with passengers to view the total solar eclipse from Vadsö, in the Varanger Fjord, on August 9. The conditions of 1851, when a small expedition observed a total eclipse from Bue Island, Norway, has given place to a new state of things; and there seems every possibility that for every one who went out to see the obscuration of the sun then, fifty will witness the phenomenon next August. The Orient Steam Navigation Company will send out two of their steamships; Messrs. Cook and Son have made arrangements for special eclipse cruises; and Messrs. Gaze and Son announce a trip to Vadsö in the *Norse King*. This steamer is due at Vadsö on August 3, which leaves sufficient time for the average sightseer to settle down to a frame of mind suitable for observing a solar eclipse. But we notice with some astonishment, in a circular issued by Messrs. Gaze and Son, the statement that "an official party of observers, arranged by a joint committee of the Royal Society and of the Astronomical Society, are proceeding to Norway, and will travel by the s.s. *Norse King*." We can hardly think that this statement is authoritative, for scientific committees are not in the habit of advertising their intention to patronise any particular line of steamers; and, further, astronomers usually require more than five days to adjust and set up their instruments, if any work of real use to science is to be done. Of course, those photographers who merely wish to take snap-shots at the corona do not need to make any elaborate preparations, and if the steamship they travel by carries them into harbour two or three days before August 9, they will have ample time to point their cameras correctly.
